Patent Ductus Arteriosus in the Preterm Infant

RONALD I. CLYMAN

KEY POINTS

- Clinical signs of a symptomatic patent ductus arteriosus (PDA) usually appear later than echocardiographic signs and are related to the degree of left-to-right ductal shunting, with associated blood flow changes to the lungs, brain, kidneys, and intestines.
- Factors known to play a prominent role in regulation of ductal patency involve those that promote constriction (oxygen, endothelin, calcium channels, catecholamines, and Rho kinase) and those that oppose it (intraluminal pressure, prostaglandins, nitric oxide, carbon monoxide, potassium channels, and cyclic adenosine monophosphate and guanosine monophosphate).
- Closure of the ductus arteriosus occurs in two phases: (1) “functional” closure of the lumen by smooth muscle constriction, within hours after birth; (2) “anatomic” occlusion of the lumen over the next several days, due to neointimal thickening and loss of smooth muscle cells from the inner muscle media.
- The most important mechanism that prevents the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of prostaglandin E_2 . As a result, inhibitors of prostaglandin production (e.g., indomethacin, ibuprofen, acetaminophen) are usually effective in promoting ductus closure in preterm infants.
- Early surgical ligation, while eliminating the detrimental effects of a PDA on lung development, may create its own set of problems for the preterm infant that counteract those benefits (e.g., postligation hypotension, bronchopulmonary dysplasia, vocal cord paralysis, neurodevelopmental abnormalities).
- While there may be general consensus on the efficacy of indomethacin for treatment of a PDA, questions about proper dosage, treatment duration, optimal timing, and treatment criteria remain controversial.
- Although a moderate-to-large PDA increases pulmonary blood flow and edema and decreases systemic blood pressure, it is not clear which is preferable: (1) to close the PDA (surgically or pharmacologically) or (2) to deal with the pulmonary edema and hypotension through other means, while awaiting spontaneous ductal closure.
- Further investigation is needed to determine which preterm infants are most likely to benefit from ductal closure and which might be best left untreated.

The ductus arteriosus represents a persistence of the terminal portion of the sixth branchial arch. During fetal life, the ductus arteriosus serves to divert blood away from the fluid-filled lungs toward the descending aorta and placenta. After

birth, constriction of the ductus arteriosus and obliteration of its lumen separate the pulmonary and systemic circulations. In full-term infants, obliteration of the ductus arteriosus takes place through a process of vasoconstriction and anatomic remodeling. In the preterm, the ductus arteriosus frequently fails to close. The clinical consequences of a patent ductus arteriosus (PDA) are related to the degree of left-to-right PDA shunt with its associated change in blood flow to the lungs, kidneys, and intestine.

Diagnosis

Phase contrast magnetic resonance imaging appears to offer the most accurate measurements of ductal shunt volume, and the effects of a PDA on left ventricular and systemic blood flow volumes (Broadhouse et al., 2014). Unfortunately these measurements are difficult to obtain in extremely immature, sick preterm infants. As a result, two-dimensional echocardiography and color Doppler flow mapping have been used as the gold standards for assessing the magnitude and direction of PDA shunting. Ductus diameter ≥ 1.5 mm (or $>50\%$ of the diameter of the left pulmonary artery), left atrial-to-aortic root (LA/Ao) ratio ≥ 1.5 , reversal of forward blood flow in the descending aorta during diastole, and end diastolic flow velocity in the left pulmonary artery ≥ 0.20 m/s are signs consistent with a moderate-to-large PDA shunt (Table 54.1) (El Hajjar et al., 2005). Unfortunately, the inter-observer repeatability of all echocardiographic parameters is relatively poor (Schwarz et al., 2016).

Clinical signs of a PDA (systolic murmur, hyperdynamic precordial impulse, full pulses, widened pulse pressure and/or worsening respiratory status) usually appear later than echocardiographic signs and are less sensitive in determining the degree of left-to-right shunt. Certain signs such as continuous murmur or hyperactive left ventricular impulse are relatively specific for a PDA but lack sensitivity; conversely, worsening respiratory status, although a sensitive indicator, is relatively nonspecific for a PDA. Tachycardia is not a useful or reliable indicator of a PDA in preterm infants. Infants with large left-to-right shunts may have evidence of cardiomegaly and increased pulmonary arterial markings on their chest X-rays; however, in general, the chest X-ray and electrocardiogram are not useful in diagnosing a PDA. Although elevated plasma concentrations of Brain Natriuretic Peptide (BNP) and N-terminal pro-BNP (NTpBNP) have been found to correlate with the presence of a moderate sized left-to-right PDA shunt,

TABLE 54.1 Rates of Spontaneous Ductus Arteriosus Closure Among Neonates Who Survive to 72 Hours

| Gestation | Closed on Day 4 % | Closed on Day 7 % | Closed at Discharge % |
|-------------|-------------------|-------------------|-----------------------|
| Full-Term | 100 | 100 | 100 |
| ≥30 Weeks | 90 | 98 | 98 |
| 28–29 Weeks | 45 | 67 | 94 |
| 26–27 Weeks | 16 | 32 | 78 |
| 24–25 Weeks | 4 | 13 | 54 |

changes in BNP and N-terminal pro-BNP (NTpBNP) concentrations have poor sensitivity and specificity in predicting increases or decreases in PDA shunt magnitude and cannot be used to replace echocardiography in the management of PDA shunts (Chen et al., 2010). Although there has been little consensus in the past about what constitutes a clinically important PDA, recent studies have shown that although moderate and large PDA shunts are associated with significant neonatal morbidities, small PDA shunts have similar outcomes as no PDA shunts (Sellmer et al., 2013; Schena et al., 2015). Whereas the magnitude of PDA shunt plays a significant role in creating neonatal morbidity, equally important factors are the duration of exposure to the shunt and the infant's ability to compensate for the shunt.

Incidence

Functional closure of the ductus occurs in almost 50% of full-term infants by 24 hours, in 90% by 48 hours, and in nearly 100% by 72 hours after birth (Reller et al., 1993). The rate of ductus closure is delayed in preterm infants; however, essentially all preterm infants who are of 30 weeks' gestation or more (including those with respiratory distress syndrome) will close their ductus by the fourth day after birth. Infants born at less than 30 weeks' gestation have a 65% incidence of persistent ductus patency beyond day 4. Even among the most immature infants (≤27 weeks' gestation), spontaneous closure can occur during the neonatal period. However, when it does occur, it usually occurs late during the neonatal intensive care unit (NICU) hospitalization (average age is 61 ± 37 days) (Reller et al., 1993; Koch et al., 2006; Nemerofsky et al., 2008; Herrman et al., 2009; Rolland et al., 2015). Among preterm infants discharged from the hospital with a persistent PDA, 86% will achieve PDA closure by 1 year of age. The remainder will require continued observation or coil closure (Herrman et al., 2009) (Table 54.1).

Factors like surfactant administration, infection, being small for gestational age, and excessive fluid administration increase the likelihood of developing a symptomatic PDA (Cotton et al., 1981; Alpan et al., 1995; Gonzalez et al., 1996; Bell et al., 2001; del Moral et al., 2007; Rakza et al., 2007). However, non-white infants and infants who receive prenatal glucocorticoids have a reduced risk of PDA (Clyman et al., 1981; Furzan et al., 1985; Cotton et al., 1991; Chorne et al., 2007; Durrmeyer et al., 2010; Waleh et al., 2015).

Regulation of Ductus Arteriosus Patency

In the full-term infant, closure of the ductus arteriosus occurs in two phases: (1) "functional" closure of the lumen within the first

hours after birth by smooth muscle constriction and (2) "anatomic" occlusion of the lumen over the next several days because of extensive neointimal thickening and loss of smooth muscle cells from the inner muscle media.

Balance Between Vasoconstriction and Vasorelaxation

Ductus arteriosus patency is determined by the balance between dilating and constricting forces. The factors known to play a prominent role in ductus arteriosus regulation involve those that promote constriction (oxygen, endothelin, calcium channels, catecholamines, and Rho kinase) and those that oppose it (intraluminal pressure, prostaglandins [PGs], nitric oxide [NO], carbon monoxide, potassium channels, and cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate [cGMP]). The relative importance of each of these factors depends on the intrauterine and extrauterine environment, the degree of ductus maturation, and the genetic background and species being studied.

In Utero Regulation

The fetal ductus normally has a high level of intrinsic tone (Kajino et al., 2001). The intrinsic tone is due to mechanisms that both depend on and are independent of extracellular calcium (Kajino et al., 2001). The contractile proteins (smooth muscle myosin, calponin, and caldesmon) are more differentiated in the ductus than they are in the adjacent aorta and pulmonary artery (Sakurai et al., 1996). In addition, the fetal ductus arteriosus is more sensitive to the contractile effects of calcium than are the aorta and pulmonary artery (Crichton et al., 1997). This may be due in part to increased Rho kinase activity in the ductus (Clyman et al., 2007). Endothelin-1 also appears to play a role in producing the elevated basal tone of the fetal ductus arteriosus (Cocceani et al., 1999).

The relative importance of the factors that oppose ductus arteriosus constriction in utero is more clearly defined than the factors that promote constriction. The elevated vascular pressure within the ductus lumen (due to the constricted pulmonary vascular bed) plays an important role in opposing ductus constriction (Clyman et al., 1989). The fetal ductus also produces several vasodilators that maintain ductus patency. Vasodilator PGs appear to be the dominant vasodilators that oppose ductus constriction in the later part of gestation. Inhibitors of PG synthesis constrict the fetal ductus both in vitro and in vivo. Prostaglandin E₂ (PGE₂) is the most potent PG produced by the ductus (Clyman et al., 1978; Cocceani et al., 1978). Ductus smooth muscle is extraordinarily sensitive to the vasodilating effects of PGE₂. PGE₂ produces ductus relaxation by interacting with PGE receptors EP₂, EP₃, and EP₄. In the ductus, all three of the EP receptors participate in vasodilation by activating adenylate cyclase (Bouayad et al., 2001). The increased cAMP concentrations inhibit the sensitivity of the contractile proteins to calcium. Inhibitors of phosphodiesterase (the enzyme that degrades cAMP) relax the ductus in utero (Toyoshima et al., 2006). Low phosphodiesterase levels in the fetal ductus account for its increased sensitivity to PGE₂ (Liu et al., 2008).

Both isoforms of the enzyme responsible for synthesizing PGs (cyclooxygenase [COX]-1 and COX-2) are expressed in the fetal ductus. In the fetal mouse, COX-2 appears to be the COX isoform responsible for producing the PGs that regulate the ductus (Loftin et al., 2001) whereas in the fetal sheep both COX-1 and COX-2 play a role in ductus patency (Takahashi et al., 2000). In addition to the PGs that are made within the ductus, the fetal ductus is

also under the influence of circulating concentrations of PGE₂. Circulating concentrations of PGE₂ appear to be of placental origin and are high in the fetus because of the reduced pulmonary clearance of circulating PGs resulting from the low fetal pulmonary blood flow (Clyman et al., 1981).

NO, formed mainly by endothelial nitric oxide synthase (eNOS), is made by the fetal ductus arteriosus and appears to play an important role in maintaining ductus patency in rodent fetuses early in gestation (Momma et al., 1999). PGE₂ and NO appear to be preferentially coupled for reciprocal compensation since cyclooxygenase inhibition upregulates NO (Sodini et al., 2008). Although NO is also made in the ductus of larger species, its importance in maintaining ductus patency under normal in utero conditions has not been conclusively demonstrated (see later in the chapter for the role of NO in fetuses exposed to indomethacin tocolysis and in premature newborns).

Carbon monoxide relaxes the ductus arteriosus. Under physiologic conditions the amount of carbon monoxide made by the ductus does not seem to affect ductus tone; however, in circumstances where its synthesis is upregulated, e.g., endotoxemia, it may exert a relaxing influence on the ductus (Cocceani et al., 1997). Hydrogen sulfide has also been identified as another endogenous factor that inhibits fetal ductus tone (Baragatti et al., 2013).

Although short term, pharmacologic inhibition of PG synthesis and signaling produces ductus constriction in utero (Momma et al., 2005); chronic inhibition of PG synthesis and signaling produces the opposite effect: a persistent patent ductus in utero and a persistent patent ductus after birth (Nguyen et al., 1997; Loftin et al., 2001). It is now clear that, in addition to its role in maintaining fetal ductus patency, PGE₂ is essential for the induction of pathways necessary for postnatal closure. Blocking PGE₂ activity by disrupting the PG EP₄ receptor decreases the expression of several genes that control postnatal oxygen-induced ductus constriction (see “in utero regulation”). Specifically, PGE₂ increases the expression of calcium L (CaL)- and potassium (K⁺)-channel genes (*CaLalpha1c*, *CaLbeta2*, *Kir6.1*, and *Kv1.5*), which regulate calcium entry, without affecting genes that regulate calcium sensitization (Rho kinase-associated genes). Chronic inhibition of PG synthesis decreases the expression of CaL- and K⁺-channel genes. Phosphodiesterase expression, which decreases the ductus’ sensitivity to cAMP- or cGMP-dependent vasodilators, is also decreased by chronic COX inhibition (Reese et al., 2009). Inhibition of PG signaling may also contribute to delayed closure by inhibiting hyaluronic acid production and intimal cushion formation in the ductus (Yokoyama et al., 2006). Intimal cushions play an important role in permanent ductus closure after birth (see “Anatomic Closure-Histologic Changes”). PGE₂, acting through its EP₄ receptor, has been shown to affect intimal thickening, elastogenesis, and contraction-related genes through pathways that involve cAMP, cAMP-protein kinase A, exchange protein activated by cAMP, phospholipase C, and Wnt/β-catenin (Yokoyama, 2015).

It is interesting to note that pharmacologic inhibition of PG synthesis in human pregnancy is also associated with an increased incidence of PDA after birth (Norton et al., 1993). However, this appears to be due to the ability of indomethacin to produce ductus constriction in utero. In utero constriction produces ischemic hypoxia, increased NO production, and smooth muscle cell death within the ductus wall (see “Relationship Between Vasoconstriction and Anatomic Closure”). These factors prevent the ductus from constricting after birth and make it resistant to the constrictive effects of postnatal indomethacin (Clyman et al., 2001; Goldbarg et al., 2002) (Box 54.1).

• BOX 54.1 Pathways Affected by In Utero Chronic Inhibition of Prostaglandin Production and Signaling That Contribute to Persistent Ductus Arteriosus Patency After Birth

Pathways Involved With Smooth Muscle Contraction

- Decreased expression of CaL-channel and K⁺-channel genes (*CaLalpha1c*, *CaLbeta2*, *Kir6.1*, and *Kv1.5*) that facilitate calcium entry into the cytoplasm during oxygen-induced constriction
- Increased nitric oxide production
- Decreased phosphodiesterase expression. Phosphodiesterases decrease the ductus’ sensitivity to cAMP or cGMP-dependent vasodilators
- Decreased expression of myocardin, an important transcriptional coactivator that regulates production of smooth muscle cell contractile proteins
- Decreased Wnt/β-catenin activation of myocardin

Pathways Involved With Neointimal Mound Formation

- Decreased hyaluronic acid production, which is important in neointimal mound formation
- Decreased hyaluronic acid dependent and Epac (exchange protein activated by cAMP) dependent smooth muscle migration into the neointimal mounds
- Decreased elastic fiber fragmentation and increased elastic fiber formation by ductus smooth muscle cells

Additional Pathways Involved When Ductus Arteriosus Depends on Vasa Vasorum to Supply Oxygen to the Outer Vessel Wall (i.e., Fetuses Older Than 28 Weeks’ Gestation)

- Collapse of vasa vasorum in the muscle media
- Ischemic hypoxia of the smooth muscle cells in the muscle media
- Increased nitric oxide production
- Smooth muscle cell death

cAMP, Cyclic adenosine monophosphate; CaL, calcium L channel; cGMP, cyclic guanosine monophosphate; K⁺, potassium ion.

Postnatal Regulation

There are several events that promote ductus constriction in the full-term newborn following delivery: (1) an increase in arterial PO₂, (2) a decrease in blood pressure within the ductus lumen (because of the postnatal decrease in pulmonary vascular resistance), (3) a decrease in circulating PGE₂ (because of the loss of placental PG production and the increase in PG removal by the lung), and (4) a decrease in the number of PGE₂ receptors in the ductus wall. Although the newborn ductus continues to be sensitive to the vasodilating effects of NO, it loses its ability to respond to PGE₂ (Abrams et al., 1995). All of these factors promote ductus constriction after birth.

The postnatal increase in arterial PO₂ plays an important role in ductus constriction. Oxygen-induced constriction occurs in the presence of inhibitors of PG, NO, and endothelin signaling. This suggests that these vasoactive substances are not essential for normoxic constriction. In most species, oxygen appears to constrict the ductus arteriosus through both mechanisms that involve smooth muscle depolarization and mechanisms that are independent of membrane depolarization (Roulet et al., 1981). Oxygen depolarizes the ductus smooth muscle cells by inhibiting K⁺ channels (Michelakis et al., 2000). Following the depolarization of the membrane, calcium enters the ductus smooth muscle through L-type (Clyman et al., 2007) and T-type (Yokoyama et al., 2006) voltage-dependent

calcium channels. Several oxygen-sensitive K^+ channels have been found in the fetal ductus (including Kv1.5 and Kv2.1). These vary with species and gestational age and may account for the differing sensitivity of the ductus to oxygen (Hayama et al., 2006; Wu et al., 2007). Oxygen also appears to have a direct effect on the CaL-channels themselves (Thebaud et al., 2008) and on the store-operated calcium channels (Hong et al., 2006). In addition, oxygen may increase smooth muscle sensitivity to calcium by activating Rho kinase-mediated pathways (Hong et al., 2006).

Unique oxygen sensors within the ductus wall have been identified; however, their relative importance has not been agreed upon due to species variations in addition to multiple interacting downstream pathways. In some species, a mitochondrial oxygen sensor within the ductus smooth muscle cells regulates K^+ and calcium channels, as well as Rho kinase activity through the production of reactive oxygen molecules such as hydrogen peroxide (H_2O_2). Elevated PO_2 causes mitochondrial fission, which increases H_2O_2 production (Hong et al., 2013; Dunham-Snary et al., 2016). In contrast, in other species H_2O_2 acts as a vasodilator (Clyman et al., 1989) or as both a vasodilator and a vasoconstrictor (depending on its concentration) (Van der Sterren et al., 2014).

The oxygen-induced constriction may also involve a cytochrome P450 hemoprotein (Baragatti et al., 2011; Ciofini et al., 2013). This is an intriguing observation since preterm infants have an increased incidence of PDA when treated with cytochrome P450 inhibitors (Cotton et al., 2013). Oxygen also activates the epidermal growth factor receptor (EGFR) in ductus smooth muscle cells, and EGFR inhibition attenuates oxygen-induced constriction. The EGFR vasoconstriction appears to be mediated through tyrosine kinases and phosphatases (Hong et al., 2014).

Oxygen also increases the formation of isoprostanes that can modulate the postnatal constriction (Chen et al., 2012), as well as the potent vasoconstrictor, endothelin-1 (Cocceani et al., 1989). The role of endothelin-1 in postnatal ductus closure is still unclear due to the marked species variation in its contribution to the oxygen-induced ductus constriction. Endothelin receptor stimulation accounts for 44% of the oxygen-induced constriction in the rat but only 13% in the rabbit. In the human ductus, inhibition of endothelin production does not inhibit oxygen-induced constriction (Fineman et al., 1998; Cocceani et al., 1999; Michelakis et al., 2000; Shen et al., 2002). The postnatal increase in PaO_2 also has profound modulatory effects on other vasoactive systems (Smith, 1998). Elevated oxygen tensions can increase the ductus' contractile response to neural mediators (Ikeda et al., 1973) and decrease the formation of vasodilator PGs (Kajino et al., 2001). Although the contractile effects of oxygen play an important role in postnatal ductus constriction, they may not be essential for postnatal ductus closure. For example, mice lacking the endothelin A receptor have diminished oxygen-induced ductus constriction; however, their ductus closes normally after birth (Cocceani et al., 1999).

Developmental Regulation

In contrast with the full-term ductus, the premature ductus is less likely to constrict after birth (Box 54.2). This is due to several mechanisms. The intrinsic tone of the extremely immature ductus (<70% of gestation) is decreased compared with the ductus at term (Kajino et al., 2001). This may be due to the presence of immature smooth muscle myosin isoforms, with a weaker contractile capacity (Colbert et al., 1996; Sakurai et al., 1996), and decreased Rho kinase expression and activity (Kajimoto et al., 2007). Calcium entry through L-type calcium channels appears to be impaired in the immature ductus (especially under hypoxic conditions)

• BOX 54.2 Factors Affecting the Constriction of the Ductus Arteriosus After Birth: Preterm Compared With Full-Term Ductus Arteriosus

Constriction of the ductus arteriosus after birth—preterm compared with full-term ductus arteriosus:

- Immature smooth muscle isoforms and decreased intrinsic tone
- Decreased calcium entry through calcium L-channels
- Decreased Rho kinase activity
- Increased potassium K_{Ca} channels (which are not regulated by oxygen)
- Decreased potassium K_v channels (which are regulated by oxygen)
- Decreased endothelin production
- Decreased pulmonary clearance of circulating prostaglandin E2
- Increased number of postnatal prostaglandin receptors (EP4)
- Increased EP4 coupling with adenylyl cyclase and increased cAMP production
- Decreased cAMP degradation by phosphodiesterases

cAMP, Cyclic adenosine monophosphate; K_{Ca} , calcium-activated potassium channel; K_v , oxygen-sensitive potassium ion channel.

(Clyman et al., 2007; Thebaud et al., 2008). The potassium channels that promote ductus relaxation also change during gestation (switching from K_{Ca} channels (which are not regulated by oxygen tension) to K_v channels (which can be inhibited by increased oxygen concentrations). Reduced expression and function of the putative oxygen-sensing K_v channels appear to contribute to ductus patency in the preterm rabbit, sheep, baboon, mouse, and chicken (Thebaud et al., 2004; Cogolludo et al., 2009; Waleh et al., 2009). In contrast, a decrease in K_v channel expression occurs with advancing gestation in the rat, which suggests that in that species ductus arteriosus closure may occur by eliminating K_v channels (Wu et al., 2007).

Premature infants have elevated circulating concentrations of PGE2, which may play a significant role in maintaining ductus patency during the first days after birth. This is due to the decreased ability of the premature lung to clear circulating PGE2 (Clyman et al., 1981). In addition, during episodes of bacteremia and necrotizing enterocolitis (NEC), circulating concentrations of PGE2 reach the pharmacologic range and are often associated with reopening of the ductus arteriosus (Gonzalez et al., 1996).

The most important mechanism that prevents the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of PGE2. The increased sensitivity to PGE2 is due to both increased cAMP production (from enhanced receptor coupling with adenylyl cyclase) and decreased cAMP degradation by phosphodiesterase (Waleh et al., 2004; Liu et al., 2008). As a result, inhibitors of PG production (e.g., indomethacin, ibuprofen, mefenamic acid, and acetaminophen) are usually effective agents in promoting ductus closure in the premature infant.

The factors responsible for the changes that occur with advancing gestation are currently unknown. Prenatal administration of vitamin A has been shown to increase both the intracellular calcium response and the contractile response of the preterm ductus to oxygen (Wu et al., 2001). However, vitamin A administration does not improve the rate of ductus closure in preterm infants (Ravishankar et al., 2003). During normal fetal development there are increases in the circulating concentrations of thyroid hormones and cortisol with advancing gestation. Thyroid hormones may play a role in ductus arteriosus maturation since full-term infants with congenital

hypothyroidism have an increased incidence of PDA that appears to respond to thyroid hormone replacement therapy (Guarnieri et al., 2008). Similarly, a lower occurrence of PDA has been found in thyroid hormone-treated preterm infants (Osborn et al., 2007). Elevated cortisol concentrations in the fetus also foster ductus maturation by decreasing the sensitivity of the ductus to the vasodilating effects of PGE₂ (Clyman et al., 1981). Prenatal administration of glucocorticoids significantly reduces the incidence of PDA in premature humans and animals (Thibeault et al., 1978; Clyman et al., 1981). Postnatal glucocorticoid administration also reduces the incidence of PDA (Vermont Oxford Network Steroid Study Group, 2001). However, postnatal glucocorticoid treatment also increases the incidence of several other neonatal morbidities (Watterberg et al., 2004).

Although PGs play a dominant role in maintaining ductus patency in the preterm ductus, they also contribute to persistent ductus patency in infants born at term. Indomethacin can produce a substantial degree of ductus constriction even among term infants (Takami et al., 2007) as well as in infants born with congenital cardiac anomalies (Takami et al., 2013).

Genetic Regulation

Both species and genetic background play a significant role in determining the relative importance of ductus regulatory pathways. There is a marked species difference among several of these pathways; for example, ductus patency is critically dependent on vasodilator PGs in most species; however, notable exceptions exist in the guinea pig, chicken, and emu ductus, where locally derived PGs do not appear to play a role in its patency (Bodach et al., 1980; Agren et al., 2007; Dzialowski et al., 2008).

Recent studies using genome-wide transcriptome analysis to examine differences in gene expression between the ductus and the aorta (as well as the effects of oxygen and birth on ductus gene expression) (Costa et al., 2006; Liu et al., 2013; Shelton et al., 2014) have found that the expression of genes controlling matrix molecules (such as fibronectin and lysyl oxidase), actin–myosin interactions, potassium and calcium ion signaling, and genes involved with PG, endothelin, and angiotensin II signaling are increased in the ductus. Mutations in several of these ductus-dominant genes (examined in either mouse knock-out models or human genetic syndromes) are associated with delayed ductus closure or a persistent PDA in term neonates (Huang et al., 1998; Segi et al., 1998; Cocceani et al., 1999; Bergwerff et al., 2000; Morano et al., 2000; Loftin et al., 2001; Zhao et al., 2001; Mani et al., 2002; Trivedi et al., 2006; Zhu et al., 2006; Chang et al., 2007; Huang et al., 2008; Ko et al., 2008; Newbern et al., 2008; Anderson et al., 2009; Choudhary et al., 2009; Chang et al., 2010; Feng et al., 2010; Peng et al., 2010; Sinibaldi et al., 2010; Banka et al., 2011; Fallahi et al., 2011; Shen et al., 2011; Zhang et al., 2011; Zhao et al., 2011; Gruzdev et al., 2012; Paterick et al., 2013; Cooper et al., 2014; Roulez et al., 2014).

Genetic or familial factors also may play a role in persistent ductus patency in preterm infants (Lavoie et al., 2008; Bhandari et al., 2009). Several single nucleotide polymorphisms (SNPs) have recently been associated with preterm PDA: angiotensin receptor-alpha gene (T/C) Pvu II polymorphism (ATR) type 1 (Treszl et al., 2003), interferon (IFN) γ (Bokodi et al., 2007), estrogen receptor- α PvuII (Derzbach et al., 2005), Transcription Factor AP-2 Beta (TFAP2B), prostacyclin synthase (PGI) synthase, and TNF receptor-Associated Factor 1 (TRAF1) (Dagle et al., 2009). These associations will need to be replicated in other studies. There is a growing body of evidence to suggest that SNPs in TFAP2B may be responsible

for some of the PDAs that occur in preterm infants. TFAP2B is uniquely expressed in ductus smooth muscle; it regulates other genes that are important in ductus smooth muscle development; mutations in TFAP2B produce PDA in mice and humans (Zhao et al., 2001); and TFAP2B polymorphisms are associated with preterm PDAs (especially those that are unresponsive to indomethacin) (Dagle et al., 2009).

Anatomic Closure—Histologic Changes

In the full-term newborn there are progressive intimal thickening and fragmentation of the internal elastic lamina after delivery. As the intima increases in size, it ultimately forms mounds that occlude the already constricted lumen. The increase in intimal thickening is due (1) to migration of smooth muscle cells from the muscle media into the intima and (2) to proliferation of luminal endothelial cells. The process of intimal cushion formation starts with the accumulation of hyaluron (HA) below the luminal endothelial cells. This is accompanied by the loss of laminin and collagen IV from the basement membrane of the endothelial cells and their subsequent separation from the internal elastic lamina. The hygroscopic properties of HA cause an influx of water and widening of the subendothelial space; this creates an environment well-suited for cell migration (Boudreau et al., 1991). The endothelial and smooth muscle cells of the ductus arteriosus differ from those of the adjacent vessels in their ability to form neointimal cushions. Isolated endothelial cells of the ductus arteriosus have an increased rate of HA accumulation compared with those of the aorta or pulmonary artery; this increase appears to be due to transforming growth factor β (Boudreau et al., 1992), which is markedly increased in the ductus after birth. PGs, acting through the EP₄ receptor, also appear to play a critical role in HA production in the ductus (Yokoyama et al., 2006). Fibronectin and chondroitin sulfate also play an important role in facilitating ductus smooth muscle cell migration (Boudreau et al., 1991).

Intimal cushion formation in the ductus is also associated with striking alterations in elastin fiber assembly. In the aorta, well-developed elastic laminae in the muscle media provide elasticity and prevent the vascular wall from collapsing. In contrast, smooth muscle cells in the ductus muscle media are surrounded by thin and fragmented elastin fibers that do not prevent it from collapsing and closing when it vasoconstricts. The disruption of normal elastin fiber assembly in the ductus does not appear to be due to increased elastase activity or decreased tropoelastin production. Rather, it appears to be due to developmental mechanisms that reduce insolubilization of elastin and prevent formation of intact elastic laminae. PGE₂ and its receptor EP₄ appear to play a critical role in inhibiting thick elastin fiber formation in the ductus. Lysyl oxidase, which catalyzes elastin cross-linking, is degraded when the EP₄ receptor is stimulated. Interestingly, the ductus of the EP₄ knock-out mouse has an increased elastic phenotype that is similar to the aorta (Yokoyama et al., 2014).

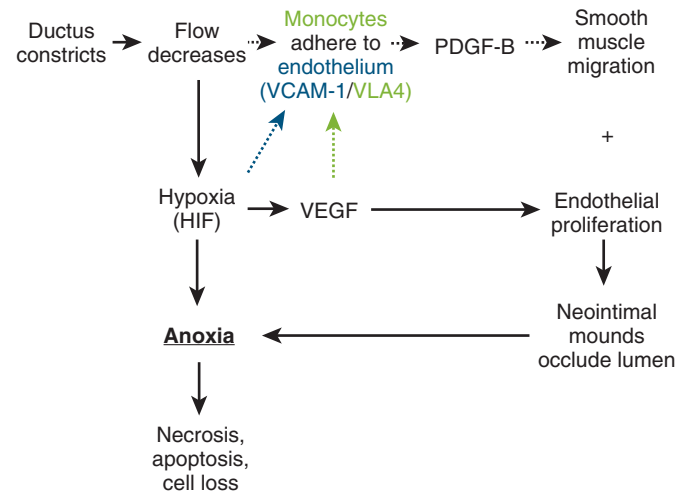

The exact relationship between impaired elastin assembly and smooth muscle migration into the neointima is still open for speculation. Impaired assembly of thick elastic laminae might facilitate smooth muscle cell migration by removing a physical barrier. In addition, truncated tropoelastin may act as a chemoattractant for smooth muscle cells (Mecham et al., 1984). Conversely, in some genetic forms of PDA, the elastic laminae of the ductus appear abnormally well developed and similar to those in the aorta; when this occurs, intimal cushions fail to develop (de Reeder et al., 1990; Hsieh et al., 2014; Yokoyama et al., 2014).

Relationship Between Vasoconstriction and Anatomic Closure

In full-term animals, loss of responsiveness to PGE₂ shortly after birth prevents the ductus arteriosus from reopening once it has constricted (Clyman et al., 1983; Abrams et al., 1995). This is due, in part, to decreased synthesis of PGE₂ receptors in the ductus after birth. Both the loss of vasodilator regulation and the anatomic events that lead to permanent closure appear to be controlled by the degree of ductus smooth muscle constriction. Experimental models that alter the ability of the ductus to constrict at term also prevent the normal histologic changes that occur after birth (Clyman et al., 1989; Nguyen et al., 1997; Loftin et al., 2001). Constriction produces ischemic hypoxia of the vessel wall (Clyman et al., 1999).

Because of the thickness of the term ductus, intramural vasa vasorum are needed to provide oxygen and nutrients to the outer half of its wall. These collapsible intramural vasa vasorum provide the ductus with a unique mechanism for controlling the maximal diffusion distance for oxygen and nutrients across its wall. Ductus constriction obliterates vasa vasorum flow to the outer muscle media, which turns the entire thickness of the muscle media into a virtual avascular zone (Kajino et al., 2002). The profound ischemic hypoxia that follows the constriction inhibits local production of PGE₂ and NO, induces local production of hypoxia inducible factors such as hypoxia inducible factor (HIF)1 α and vascular endothelial growth factor (VEGF), and produces smooth muscle apoptosis in the ductus wall. VEGF plays a critical role in the migration of the ductus smooth muscle cells into the neointima and in the proliferation of intramural vasa vasorum (Clyman et al., 2002). After postnatal ductus constriction, several genes known to be essential for vascular remodeling (*HIF1 α* , *VCAM-1*, *E-selectin*, *interleukin [IL]-8*, *MCSF-1*, *CD154*, *IFN γ* , *IL-6*, and *tumor necrosis factor [TNF]- α*) are increased in the ductus wall. Circulating mononuclear cells are attracted to the ductus, and, once adherent to the ductus wall, they become activated monocytes/macrophages and produce platelet derived growth factor (PDGF), which stimulates smooth muscle migration and proliferation within the neointima. The inflammatory response that follows postnatal ductus constriction appears to be necessary for neointimal remodeling since the extent of remodeling is determined by the degree of mononuclear cell adhesion (Waleh et al., 2005) (Fig. 54.1).

In preterm infants, the ductus frequently remains open for many days after birth. Even when it does constrict, the premature ductus frequently fails to develop profound hypoxia and anatomic remodeling. The preterm infant requires a greater degree of ductal constriction than the term infant to develop a comparable degree of hypoxia. In contrast with the term ductus, the thin-walled preterm ductus does not depend on intramural vasa vasorum to provide oxygen and nutrients to its wall. Before 26 weeks' gestation, intramural vasa vasorum are absent from the ductus wall. The absence of intramural vasa vasorum leaves the preterm ductus without a mechanism to rapidly increase the diffusion distance across its wall during postnatal constriction. As long as any degree of luminal patency exists, the thin-walled preterm ductus fails to become profoundly hypoxic and fails to undergo anatomic remodeling after birth. As a result, the preterm ductus requires complete cessation of luminal flow before it can develop the same degree of hypoxia as found at term. Once the preterm ductus develops the same degree of hypoxic ischemia as the term ductus, most of the anatomic changes seen at term will occur (Seidner et al., 2001). However, if the premature ductus does not develop the degree of

• **Fig. 54.1** Ductus Remodeling: Role of Constriction, Hypoxia, and Mononuclear Cell Adhesion in Neointima Formation and Smooth Muscle Cell Death. Postnatal constriction produces hypoxia in the ductus wall. The hypoxic smooth muscle and endothelial cells increase their expression of vascular endothelial growth factor (VEGF) and VCAM-1, respectively. VEGF is required for endothelial cell proliferation. VEGF also attracts circulating mononuclear cells (expressing VLA-4) to the endothelial cell surface. Under very low flow conditions, the weakly adherent VLA-4⁺ mononuclear cells attach to VCAM-1 on the endothelial cell surface and release platelet derived growth factor and matrix metalloproteinase 9 (which promote smooth muscle migration into the neointima). Tight constriction and loss of luminal flow are essential for VEGF expression, mononuclear cell adhesion, neointimal formation, and luminal occlusion. *HIF*, hypoxia inducible factor; *MMP-9*, matrix metalloproteinase-9; *PDGF-B*, platelet derived growth factor B; *VCAM-1*, vascular cell adhesion molecule-1; *VEGF*, vascular endothelial growth factor; *VLA-4*, integrin very late antigen-4.

ischemic hypoxia needed to induce cell death and anatomic remodeling, it will continue to be responsive to vasodilators and continue to be susceptible to vessel reopening.

Although inhibitors of PG production are very effective in closing the ductus when given on postnatal day 1, they become less effective by the end of the first postnatal week. A number of factors conspire to make the postnatal preterm ductus increasingly resistant to indomethacin-induced and ibuprofen-induced closure. In contrast to the term newborn ductus, where all of the PGE₂ EP receptors are downregulated after birth, the preterm newborn ductus increases its synthesis of the dominant PGE₂ receptor, EP₄, and continues to respond to PGE₂ after birth. In addition to its persistent responsiveness to PGE₂, the premature ductus synthesizes increased amounts of other vasodilators (e.g., NO, TNF- α , and IL-6) after birth in response to the postnatal ductus wall hypoxia (Waleh et al., 2005). As a result, a change occurs in the relative balance of the vasodilators that maintain ductus patency after birth. Ductus patency becomes less dependent on PG generation and more dependent on other vasodilators after the first few days following birth. In addition, adenosine triphosphate concentrations are significantly altered in the preterm PDA. The decreased adenosine triphosphate concentrations prevent the immature neonatal ductus from contracting as vigorously as the fetal ductus (Levin et al., 2005). As a result of these postnatal changes, the effectiveness of indomethacin and ibuprofen wanes with increasing postnatal age (Clyman, 1996). In premature animals and humans, the combined use of an NO synthase inhibitor and indomethacin produces a much greater degree of ductus constriction than

indomethacin alone. It follows that drugs that interfere with NO synthesis could become a useful adjunct, especially in situations where indomethacin has been found to be ineffective (Seidner et al., 2001; Keller et al., 2005).

Hemodynamic and Pulmonary Alterations

The pathophysiologic features of a PDA depend both on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to the shunt. There are important differences between immature and mature infants in the heart's ability to handle a volume load. The immature fetal ventricles have less cardiac sympathetic innervations, are less distensible than at term, and generate less force per gram of myocardium (Romero et al., 1979). The relative lack of left-ventricular distensibility in immature infants is more a function of the ventricle's tissue constituents than of poor muscle function. As a result, left-ventricular distention secondary to a large left-to-right PDA shunt may produce a higher left-ventricular end-diastolic pressure at smaller ventricular volumes. The increase in left-ventricular pressure increases pulmonary venous pressure and causes pulmonary congestion.

Studies in preterm animal and human newborns (Clyman et al., 1987; Shimada et al., 1994) have shown that, despite these limitations, preterm newborns are able to increase left-ventricular output and maintain their "effective" systemic blood flow, even with left-to-right PDA shunts equal to 50% of left-ventricular output. With shunts greater than 50% of left-ventricular output, "effective" systemic blood flow falls, despite a continued increase in left-ventricular output. The increase in left-ventricular output associated with a PDA is accomplished not by an increase in heart rate but by an increase in stroke volume. Stroke volume increases primarily as a result of the simultaneous decrease in afterload resistance on the heart and the increase in left-ventricular preload. Despite the ability of the left ventricle to increase its output in the face of a left-to-right ductus shunt, blood flow distribution is significantly rearranged. Blood flow to the gastrointestinal (GI) tract and kidneys is decreased due to a combination of decreased perfusion pressure and localized vasoconstriction. Mesenteric blood flow is decreased in both fasting and fed states in the presence of a PDA (McCurnin, Clyman, 2008). Significant decreases in organ blood flow occur before there are signs of left-ventricular compromise (Shimada et al., 1994) and may contribute to the decreased glomerular filtration rate (Clyman, 1996) that has been observed with ductus patency. Cerebral blood flow and oxygenation are also compromised in the presence of a moderate PDA left-to-right shunt because of the preterm newborn's limited ability to autoregulate its cerebral vascular bed (Lemmers et al., 2010).

The decreased ability of the preterm infant to maintain active pulmonary vasoconstriction may be responsible in part for early development of a "large" left-to-right PDA shunt. Randomized controlled trials have shown that the presence of a PDA increases the incidence of early hemorrhagic pulmonary edema/pulmonary hemorrhage (Al Faleh et al., 2008; Aranda et al., 2009; Kluckow et al., 2014). Therapeutic maneuvers or prenatal conditions that lead to a rapid postnatal drop in pulmonary vascular resistance, such as surfactant replacement or intrauterine growth retardation, can exacerbate the amount of left-to-right shunt and lead to pulmonary hemorrhage (Alpan et al., 1995; Rakza et al., 2007). Although phototherapy has been associated with persistence of a PDA, randomized controlled trials (RCTs) have not found that chest shielding alters the incidence or severity of PDA (Bhola et al., 2015).

In premature animals, a wide open PDA increases the hydraulic pressures in the pulmonary vasculature on both the arterial and venous sides of the capillary bed. In addition, the increase in pulmonary blood flow and immature precapillary arterial tone shift the distribution of intravascular hydraulic pressures toward downstream capillary fluid filtration sites (Perez Fontan et al., 1987). This, in turn, increases the rate of fluid transudation into the pulmonary interstitium (Alpan et al., 1991). Any increase in microvascular perfusion pressure in premature infants with respiratory distress syndrome may increase interstitial and alveolar lung fluid because of their low plasma oncotic pressures and increased capillary permeability. Leakage of plasma proteins into the alveolar space inhibits surfactant function, increases surface tension, and decreases compliance of the immature air sacs (Ikegami et al., 1983), which are already compromised by surfactant deficiency. The increased fraction of inspired oxygen and mean airway pressures required to overcome these early changes in compliance may play a role in the development of chronic lung disease. Depending on the gestational age and the species examined, changes in pulmonary mechanics may occur as early as 1 day after birth or not before several days of exposure to a PDA left-to-right shunt (Perez Fontan et al., 1987; McCurnin et al., 2008).

Although preterm animals with a PDA have increased fluid and protein clearance into the lung interstitium (which is due to an increase in pulmonary microvascular filtration pressure), a simultaneous increase in lung lymph flow appears to eliminate the excess fluid and protein from the lung (Alpan et al., 1991). This compensatory increase in lung lymph acts as an "edema safety factor," inhibiting fluid accumulation in the lungs. As a result, there is no net increase in water or protein accumulation in the lung, and there is no change in pulmonary mechanics (Perez Fontan et al., 1987; Alpan et al., 1989; Clyman, 1996). This delicate balance between the PDA-induced fluid filtration and lymphatic reabsorption is consistent with the observation, made in human infants, that closure of the ductus arteriosus within the first 24 hours of birth has no effect on the course of the newborn's hyaline membrane disease. However, after several days of mechanical ventilation, there is a decrease in pulmonary capillary surface area (Mokres et al., 2010), which increases both the pulmonary microvascular pressure and rate of hydraulic fluid filtration. As a result, it is not uncommon for infants with a persistent PDA to develop pulmonary edema and alterations in pulmonary mechanics at 6 to 10 days after birth. In these infants, improvement in lung compliance occurs following closure of the PDA (Clyman 1996; Szymankiewicz et al., 2004).

Preterm baboon newborns, delivered at 67% term gestation and mechanically ventilated for 2 weeks, have been used to examine the effects of a PDA on pulmonary mechanics (McCurnin et al., 2008). Preterm baboons were either treated with a cyclooxygenase inhibitor to close the PDA or allowed to have a persistent PDA. Exposure to a persistent PDA for 2 weeks did not appear to alter surfactant secretion, pulmonary epithelial protein permeability, or presence of surfactant inhibitory proteins in the alveoli, nor did the presence of a PDA alter the expression of proinflammatory or tissue remodeling genes. In contrast with full-term baboons, which mobilize lung fluid rapidly after birth, preterm newborns (with either an open and closed ductus) mobilize lung fluid much more slowly. As a result, a persistent PDA led to a small but significant increase in lung water at 2 weeks after delivery. In addition, closure of the PDA with indomethacin or ibuprofen produced increased expression of alveolar epithelial sodium channels, which facilitate fluid removal from the alveolar compartment (McCurnin et al.,

2008). This finding may account for the decreased incidence of significant pulmonary edema and hemorrhage in infants treated with prophylactic indomethacin after birth (Al Faleh et al., 2008; Aranda et al., 2009; Kluckow et al., 2014).

Pharmacologic closure of the PDA was associated with improved lung development in the preterm baboons. In contrast to the animals with an open ductus, where an arrest in alveolar development (the hallmark of the “new” bronchopulmonary dysplasia [BPD]) was noticeable by 2 weeks after birth, pharmacologic closure of the PDA led to improved alveolarization (McCurnin et al., 2008). Whether the improvement in alveolarization was due to the closure of the ductus or the pharmacologic agents (indomethacin/ibuprofen) used to close it is unknown at this time.

The same improvements in pulmonary mechanics and alveolar surface area have not been observed after surgical ligation of the PDA. Early surgical ligation increases the expression of genes involved with pulmonary inflammation and decreases the expression of genes associated with pulmonary epithelial sodium channels (which are critical for alveolar water clearance) (Waleh et al., 2011). These changes may contribute to the lack of improvement in pulmonary mechanics after PDA ligation. In addition, early surgical ligation impedes lung growth (Chang et al., 2008). These findings raise the possibility that early ductus ligation, while eliminating the detrimental effects of a PDA on lung development, may create its own set of problems that counteract many of the benefits derived from ductus closure (Clyman et al., 2009).

Not all of the changes associated with a PDA are necessarily detrimental to the immature infant with respiratory distress syndrome. Persistence of the left-to-right shunt maintains an elevated PaO_2 in the presence of atelectasis. This phenomenon is due to recirculation of oxygenated arterial blood through lungs that are not fully expanded (Clyman et al., 1987). Closing the PDA can lead to decreases in systemic arterial oxygen content despite the absence of any alterations in pulmonary mechanics.

Treatment

Treatment Options for Closing a PDA

In full-term infants, transcatheter PDA ligation is the treatment of choice for closing a PDA. However, its use in the premature population is just beginning to be explored (Zahn et al., 2015).

Open surgical ligation produces definitive ductus arteriosus closure; however, it is associated with several important morbidities: thoracotomy and exposure to surgical anesthesia, pneumothorax, chylothorax, scoliosis, and infection. In addition, following PDA ligation, between 20% and 60% of extremely low birth weight (ELBW) infants will develop unilateral vocal cord paralysis (which increases the requirements for tube feedings and respiratory support and persists well beyond the neonatal period) (Nichols et al., 2014; Strychowsky et al., 2014). Profound hypotension during the postoperative period is another complication that affects 30%–50% of infants with birthweights of 1000 g and lower. The incidence of profound postoperative hypotension is inversely related to the infant's corrected age and appears to be due to impaired adrenal stimulation, low cortisol release, and decreased vascular tone (Clyman et al., 2014; Noori et al., 2015). Early surgical ligation also contributes to the development of BPD (Chorne et al., 2007; Clyman et al., 2009). Neurodevelopmental abnormalities are also more frequent following early PDA ligations. If surgical expertise is not readily available, neonatal transport to another facility may be required. Therefore avoiding or delaying ligation appears to be

beneficial since many of the morbidities associated with ligation (postligation hypotension [Teixeira et al., 2008], vocal cord paralysis [Smith et al., 2009], BPD [Clyman et al., 2009]) and abnormal neurocognitive development (Wickremasinghe et al., 2012) appear to be reduced when ligation is delayed (Sung et al., 2014).

Inhibition of PG synthesis with nonselective inhibitors of COX-1 and COX-2 (indomethacin and ibuprofen) appears to be an effective alternative to surgical ligation. However, both have been associated with several potential adverse effects in the newborn. Indomethacin produces significant reductions in renal (Pezzati et al., 1999), mesenteric (Van Bel et al., 1990), and cerebral blood flow (Van Bel et al., 1989). Indomethacin also reduces cerebral oxygenation (Patel et al., 2000). Alterations in creatinine clearance and oliguria (which are minimally responsive to dopamine or furosemide therapy) are common problems. Furosemide, when used in combination with indomethacin, actually increases the incidence of acute renal failure (Brion et al., 2001). Renal function returns to normal after the initial doses of indomethacin or after drug discontinuation (Seyberth et al., 1983). There are some reports that COX inhibitors may affect glomerular development in neonatal animals; however, these findings have not been consistently observed (Bueters et al., 2013; Kent et al., 2014; Bueters et al., 2015). The action of indomethacin on these organ systems may not be due entirely to its inhibition of PG synthesis (Chemtob et al., 1991; Malcolm et al., 1993; Speziale et al., 1999). Indomethacin also has effects on lipoxygenase activity and histamine and endothelin release, although the relevance of these effects to any neonatal morbidities is still unknown.

Although indomethacin produces significant physiologic alterations and has been associated with several morbidities, none of the controlled randomized trials that have examined the relationship between indomethacin and neonatal morbidity have found an increase in the incidence of NEC, GI perforation, retinopathy of prematurity (ROP) chronic lung disease, or cerebral white matter injury following indomethacin treatment (Fowlie et al., 2003). Indomethacin, by itself, has not been shown to increase the incidence of GI perforations; however, the combination of indomethacin and postnatal steroids, administered simultaneously, does increase the incidence of GI perforations/NEC (Watterberg et al., 2004; Peltoniemi et al., 2005).

The cerebral vasoconstrictive effects of indomethacin are frequently cited as a concern for neonatologists (Edwards et al., 1990); however, a Cochrane systematic review found that indomethacin prophylaxis is more likely to decrease rather than increase the incidence of periventricular leukomalacia (Fowlie et al., 2003). There is no evidence that prophylactic indomethacin has any adverse effect on neurodevelopmental outcome at 18 months (Schmidt et al., 2001); in fact, there is evidence that it may have long-term benefits at 4.5 and 8 years (Vohr et al., 2003; Ment et al., 2004).

While there may be general consensus on the efficacy of indomethacin for treatment of a PDA, questions about proper dosage, treatment duration, and optimal timing of treatment remain quite controversial. The plasma clearance of indomethacin depends on postnatal age. Therefore a dosing regimen recommended for infants at the end of the first week (when the half-life of the drug is 21 hours) (Yaffe et al., 1980; Yeh et al., 1989) may lead to elevated and prolonged plasma concentrations when used in infants on day 1 (when the half-life is 71 hours). Conversely, a single loading dose of indomethacin (0.2 mg/kg), without subsequent maintenance doses, can be effective in closing a PDA when administered within the 24 hours following delivery (Krueger et al., 1987).

Many variations in dosage regimens have been evaluated (Gork et al., 2008). A prolonged low-dose course of indomethacin (0.1 mg/kg every 24 hours for 5–7 days) may increase the rate of permanent closure, especially in infants who still have residual ductus flow after completing the standard short course (2–3 doses over 24 hours), and may decrease the impairment of renal function from indomethacin (Hammerman et al., 1990). This dosage regimen still needs further evaluation since a higher NEC rate was observed in infants receiving prolonged maintenance indomethacin (Herrera et al., 2007). Although some have suggested that the dose of indomethacin be increased when conventional dosing fails to produce ductus closure (Sperandio et al., 2005), an RCT examining this approach found that the rate of ductus closure was not substantially improved despite a nearly threefold increase in serum indomethacin concentrations. More worrisome was the fact that the higher indomethacin concentrations produced significant increases in the incidence of moderate/severe ROP and late renal dysfunction (Jegatheesan et al., 2008).

The postnatal age at which indomethacin is administered plays an important role in determining its effectiveness. With advancing postnatal age, dilator PGs play less of a role in maintaining ductus patency (see Relationship Between Vasoconstriction and Anatomic Closure) (Cotton et al., 1991; Chorne et al., 2007). Even when indomethacin concentrations have been maintained in the “desired” range, the drug’s ability to produce complete ductus closure declines during the first days after birth. Despite its decreased effectiveness, it may still be advisable to attempt PDA closure by indomethacin before surgical ligation even in cases of advanced postnatal age (Sterniste et al., 1998).

Recurrence of a symptomatic PDA can occur after initial successful treatment. The rate of reopening, which is greatest among the most immature infants, appears to be related to the timing and completeness of ductus closure after the first treatment course (Narayanan et al., 2000). Permanent anatomic closure requires tight constriction of the ductus lumen and the development of ductus wall hypoxia (see Relationship Between Vasoconstriction and Anatomic Closure). Unfortunately, there are limitations in the ability of Doppler ultrasound to detect complete luminal closure. Even when there is no evidence of ductus patency on the Doppler/echocardiogram, a significant number of preterm infants will still have a tiny patent ductus lumen. In addition, the thinner the ductus wall, the less the likelihood that profound hypoxia and anatomic remodeling will occur. Both increasing degrees of immaturity and increasing degrees of growth restriction increase the treatment failure rate (Madeleneau et al., 2015). Twenty percent of PDAs in neonates delivered before 26 weeks reopen in spite of echocardiographic evidence of closure; in contrast, only 9% of those in neonates delivered between 26 and 27 weeks will reopen if the ductus is found to be closed on echocardiography. Early treatment produces a tighter degree of ductus constriction and as a result produces higher rates of ductus wall hypoxia and permanent closure (Narayanan et al., 2000). Recurrence of a PDA can also occur after bacterial infections (Gonzalez et al., 1996). Bacterial endotoxin increases NO production, but not PG production, in the ductus wall (Kajimura et al., 2016). This may explain why indomethacin is less effective in closing the PDA after infection.

Ibuprofen, another nonselective cyclooxygenase inhibitor, appears to be as effective as indomethacin in producing PDA closure (at least in infants with a mean gestational age of 28 weeks) (Van Overmeire et al., 2000). Compared with indomethacin, ibuprofen treatment results in reduced rates of NEC and transient renal

insufficiency (Ohlsson et al., 2015). Orogastic administration of ibuprofen appears to be as effective as intravenous administration (Ohlsson et al., 2015). In contrast with indomethacin, ibuprofen does not appear to affect mesenteric blood flow and has less of an effect on renal perfusion, oliguria, and cerebral blood flow (Malcolm et al., 1993; Mosca et al., 1997; Pezzati et al., 1999; Speziale et al., 1999; Patel et al., 2000). Animal studies suggest that ibuprofen may have some cytoprotective effects in the intestinal tract (Grosfeld et al., 1983). Unfortunately, most of the studies that have compared ibuprofen with indomethacin have not included ELBW infants (≤ 25 weeks’ gestation), which is the group that is most resistant to pharmacologic ductus closure and where the optimal age-appropriate dosing schedule for ibuprofen is still under consideration (Hirt et al., 2008). Some of the higher ibuprofen dose options are concerning because of the effects of ibuprofen on total and free serum bilirubin concentrations (Zecca et al., 2009). Ibuprofen does not have the same effects as indomethacin on cerebral autoregulation. As a result, prophylactic ibuprofen does not appear to have the same intracranial hemorrhage (ICH) sparing effect that is seen with indomethacin (see Indomethacin and Intracranial Hemorrhage (ICH)). Oral ibuprofen has been reported to have a high incidence of adverse GI events when administered prophylactically (Kanmaz et al., 2013).

Paracetamol (acetaminophen) may be an effective agent for inducing PDA closure. Although its mechanism of action has not been fully elucidated, the vasoconstrictive effect of acetaminophen appears to be mediated through inhibition of the peroxidase moiety of PGH2 synthetase (Allegraert et al., 2013). Three RCTs found oral paracetamol to have comparable effectiveness in closing the PDA with oral ibuprofen or intravenous indomethacin (Dang et al., 2013; Oncel et al., 2014; Dash et al., 2015). These results should be interpreted with caution since only a limited number of relatively mature neonates (mean gestational age greater than 28 weeks) have been treated in the paracetamol RCTs so far. In addition, since paracetamol use in pregnancy has been associated with an increased risk of infantile autism with hyperkinetic symptoms (Liew et al., 2014), long-term follow-up studies will be needed before paracetamol can be fully adopted as an alternative to indomethacin and ibuprofen.

Indomethacin and Intracranial Hemorrhage

Previous studies have shown that indomethacin can decrease the incidence of ICH in preterm infants and experimental animals (this has not been the case with ibuprofen or paracetamol). The effects of indomethacin on ICH do not appear to be due to its effects on ductus patency (Ment et al., 1988). Indomethacin decreases cerebral blood flow, decreases reactive postasphyxial cerebral hyperemia, and accelerates maturation of the germinal matrix microvasculature (Ment et al., 1992; Ballabh, 2014). Since most ICHs occur within the first 3 days of birth, one would expect to see beneficial effects only when indomethacin is given in a *prophylactic* strategy (anytime during the first 18 hours after birth [Mirza et al., 2013]). When prophylactic indomethacin is given to infants with normal echoencephalograms, there is a significant reduction of all grades (I–IV), as well as the most severe grades (III, IV) of ICH. Fortunately, when indomethacin is given to infants with a preexisting intraventricular hemorrhage (IVH) there does not appear to be an increased risk of parenchymal extension of the hemorrhage (Ment et al., 1994). However, it should be noted that infants who are coagulopathic or have low platelet counts (below $100 \times 10^9/L$) at the time COX inhibitors are

administered are at increased risk for intracerebral bleeding (Brunner et al., 2013).

PDA and Neonatal Morbidity: To Close or Not to Close

Clear evidence is lacking for or against many of the approaches to PDA treatment. Although a prolonged, persistent moderate-to-large left-to-right shunt through a PDA shortens the life span of animals and humans (Campbell 1968; Loftin et al., 2001), there has been a growing debate in recent years about whether or not the PDA needs to be closed during the neonatal period (Bose et al., 2006; Benitz et al., 2016). Preterm infants have a high rate of spontaneous PDA closure during the first 2 years. Therefore early treatment runs the risk of exposing infants to drugs or procedures they might not need. Although a moderate-to-large PDA increases pulmonary blood flow and edema and decreases systemic blood pressure, it is not clear which is preferable: (1) to close the PDA (either surgically or pharmacologically) or (2) to deal with the pulmonary edema and hypotension through other means while awaiting spontaneous ductus closure. For example, dopamine can decrease PDA shunting by increasing pulmonary vascular resistance (Bouissou et al., 2008); fluid restriction can minimize PDA symptoms (Bell et al., 2001) but fails to reduce the PDA shunt (and also is associated with reduced systemic blood flow [De Buyst et al., 2012]); and modest increases in end-expiratory pressure can improve pulmonary edema and compliance but have only a modest effect on the left-to-right PDA shunt (Fajardo et al., 2014).

Published RCTs provide only a limited amount of information to help guide current PDA treatment choices. Most of our information about the risks and benefits of indomethacin treatment comes from studies that compared two different forms of indomethacin treatment: prophylactic treatment (i.e., starting indomethacin within 12 hours of birth, before the onset of symptoms) versus symptomatic treatment (i.e., delaying treatment until PDA-related symptoms appear, which usually occur by 2–8 days after birth). Unfortunately, the trials were not designed to address the question of whether to close the PDA or to leave it alone. Prophylactic treatment (compared with waiting until the end of the first postnatal week before deciding to treat the PDA) did not decrease the incidence of important morbidities such as BPD, NEC, or neurodevelopmental impairment and resulted in overtreatment of 40%–50% of the infants that would have had spontaneous ductus closure by day 7. On the other hand, prophylactic treatment decreased a number of short-term morbidities: (1) severe early pulmonary hemorrhages, (2) severe grades of IVH, (3) the risk of developing a symptomatic PDA, (4) dopamine-dependent hypotension, (5) the need for higher levels of ventilator support, and (6) the need for surgical PDA ligation (Schmidt et al., 2001; Fowlie et al., 2003; Koch et al., 2006; Al Faleh et al., 2008; Clyman et al., 2008; Kluckow et al., 2014).

Little information exists about the consequences of even longer exposure to a persistent, symptomatic, moderate-to-large PDA shunt. Only two small RCTs, performed more than 30 years ago, specifically examined the role of a persistent untreated symptomatic PDA on neonatal morbidity (Cotton et al., 1978; Kaapa et al., 1983). Both studies found that a persistent PDA prolonged the need for respiratory support and increased pulmonary morbidity. Whether these findings are still applicable in the setting of modern neonatal respiratory care, with “gentle ventilation” and acceptance of elevated arterial partial pressure of carbon dioxide, needs to be reexamined. It is interesting that even the authors of the original

studies speculated that the PDA might not be source of the respiratory morbidity they observed. They attributed the cause of the respiratory morbidity to the “extensive use of mechanical ventilation,” used to control the PDA-induced pulmonary edema (Cotton et al., 1978).

The role of a PDA in the development of spontaneous intestinal perforation or NEC is even more controversial. Retrospective population-based observational studies have reported opposing results. There are no RCTs in the medical literature that specifically address this issue nor is there information about the advisability of continuing or stopping enteral feeding in the presence of a PDA or during its treatment. Although the presence of a PDA and indomethacin treatment are both known to decrease postprandial mesenteric blood flow, several large population-based studies (Kelleher et al., 2014; Louis et al., 2016) and a recent RCT (Clyman et al., 2013) found that infants receiving small “trophic” enteral feeds during indomethacin treatment attain full enteral feedings (without any adverse GI outcomes) at a faster rate than those kept nil per os during treatment.

In the United States, 95% of neonatologists believe that a moderate-to-large PDA should be treated if it persists in ELBW infants who continue to require mechanical ventilation or vasopressor support; in contrast, less than 30% use indomethacin prophylactically (Jhaveri et al., 2009). The number of neonatologists that treat a persistent PDA when it occurs in infants who do not require mechanical ventilation or vasopressor support varies significantly by geographic region. Marked differences in neonatologists’ willingness to feed infants in the presence of a PDA appear to account for the large geographic variations in indomethacin use and rates of PDA ligation. It is interesting to note that at one time, 70% of US neonatologists believed that enteral feedings needed to be stopped in the presence of a PDA whereas, at the same time, non-US neonatologists had exactly the opposite opinion: 70% believed that enteral feedings should continue in the presence of a PDA (Jhaveri et al., 2009).

A Personalized Approach

A moderate-to-large left-to-right PDA shunt can lead to dopamine-dependent systemic hypotension and increased ventilator needs. The University of California, San Francisco (UCSF) NICU’s approach has been to use pharmacologic treatment early in the newborn period since early pharmacotherapy has only been linked to transient renal dysfunction, and early treatment is more likely to result in successful ductus closure. In certain settings (where ICH, pulmonary hemorrhage, and PDA ligations are frequent occurrences), indomethacin prophylaxis may even be a preferred alternative. On the other hand, ductus ligation, while eliminating one potential cause for neonatal morbidity, may introduce its own set of problems. Further investigations will be needed to determine which infants are most likely to benefit from surgical ligation and which infants might best be left untreated when pharmacologic approaches are no longer an option.

Congenital Heart Disease

THOMAS SCHOLZ AND BENJAMIN E. REINKING

KEY POINTS

- Congenital heart disease (CHD) is the most common birth heart defect encountered in the clinical setting, affecting 1% of live births.
- Surgical outcomes for all forms of CHD continue to improve. Early detection through fetal echocardiography, physical examination, and pulse oximetry screening allows for improved neonatal management and decreased short-term and long-term morbidity.
- The etiology of CHD remains elusive in many cases. Advances in cellular biology and genetic testing will continue to improve our understanding of its origins.
- An in-depth understanding of neonatal cardiac anatomy and physiology is necessary for proper management of infants with CHD.

Congenital heart disease (CHD) is the most common birth defect encountered in the clinical setting. The prevalence of all forms of congenital heart lesions is approximately 1% of live births, although estimates in the newborn are likely compromised by underdiagnosis of some lesions such as bicuspid aortic valve and overdiagnosis of normal structures that are in transition, including the foramen ovale and ductus arteriosus. The presentation of the newborn with CHD can range from being asymptomatic to complete cardiovascular collapse. Most commonly, neonates with CHD present with a murmur, cyanosis, and/or congestive heart failure (CHF). Lesions that result in each of these clinical findings will be considered separately although considerable overlap exists among the three groups.

General Considerations

Fetal-to-Postnatal Transition

The hemodynamic state of the fetus is much different from the newborn. In the fetus, a relatively low systemic vascular resistance exists because of the presence of the placenta, and the pulmonary vasculature maintains a high resistance. Central shunts exist that provide alternate routes on the venous side (ductus venosus), within the heart (foramen ovale), and on the arterial side of the circulation (ductus arteriosus).

The ductus venosus predominantly collects oxygen-rich and nutrient-rich blood from the placenta via the umbilical vein and delivers this blood directly to the right atrium, largely bypassing the hepatic and portal venous systems. Based on studies in fetal

sheep, less than one-half of the umbilical venous return enters the left lobe of the liver and reaches the ductus venosus near its insertion into the inferior vena cava (IVC), returning as relatively nutrient-rich blood (Edelstone et al., 1978). The lateral position of the IVC within the right atrium results in streaming of this nutrient-rich blood across the foramen ovale and into the left atrium. The most desaturated blood to return to the right atrium comes from the coronary sinus, which combines with the venous return from the superior vena cava (SVC) and is directed across the tricuspid valve into the right ventricle.

In the fetus, the presence of the ductus arteriosus, which is nonrestrictive, results in both ventricles being subjected to a comparable afterload. Compared with the postnatal heart, this results in an increase in right ventricular workload and some restriction to filling of the right ventricle. The nutrient-rich blood deriving from the umbilical vein, which has crossed the foramen ovale to enter the left side of the heart, predominantly supplies the heart and brain. Output from the right ventricle supplies the lungs (less than 8% of the combined cardiac output) and flows right-to-left through the ductus arteriosus to supply the remainder of the body.

At birth, several important transitions take place that allow the fetus to adapt to extrauterine life. First, the gradual decline in pulmonary vascular resistance (PVR) that was occurring during the last trimester of pregnancy undergoes an abrupt drop with the first breath taken by the newborn (Fig. 55.1). This decline in PVR results in a more than 20-fold increase in pulmonary blood flow and reversal of flow (left-to-right) in the ductus arteriosus before its closure (Teitel, 1988). Second, the central shunts present in the fetus undergo closure such that blood flows in series through the body. The ductus venosus closes largely because of lack of flow following separation of the placenta, although some contractile elements may be present in the vessel wall (Adeagbo et al., 2004). The foramen ovale becomes occluded as the flap of the septum primum abuts the septum secundum following the increased pulmonary blood flow that increases filling of the left atrium. Small residual left-to-right shunts at the foramen ovale may persist although will generally decrease with time (see “Atrial Septal Defects” later in the chapter). Closure of the ductus arteriosus is mediated by a variety of pathways, although patency of the ductus can usually be maintained by exogenous prostaglandin administration. The third important transition at birth is an increase in the combined ventricle output as the metabolic demands of the body increase at birth.

• **Fig. 55.1** Change in Pulmonary Vascular Resistance. A gradual decline in pulmonary vascular resistance is seen during the latter part of gestation followed by an abrupt decline at birth. A gradual decline occurs postnatally over the next 6–8 weeks.

The dramatic hemodynamic changes that occur at birth continue to evolve over the next few months. There is a continued decline in PVR during the first 6–8 weeks after birth. In addition, the right ventricle remodels to a thinner and more compliant ventricle. Probe patency of the foramen ovale may persist for years, although in most individuals the septa become adherent.

Nomenclature

The complete description of any heart requires more than a description of the presence or absence of a specific congenital heart defect. Each heart has a specific set of structures and connections that may be normal or abnormal. While the terminology used for cardiac lesions is relatively consistent among pediatric cardiologists, different nomenclatures have been developed to completely define the cardiac anatomy and various systems have evolved that are based on surgical approaches, embryologic origins, or spatial relationships, which has hampered communication between individuals and institutions. A common method of describing cardiac anatomy would be a benefit but seems unlikely to be agreed upon in the near future. While the brief summary of nomenclature that is given here is based on the segmental approach of [Anderson et al. \(1984\)](#), the embryologic approach of [Van Praagh \(1972\)](#) is equally valid and used by several institutions.

The segmental approach to describing cardiac anatomy includes:

1. Cardiac position
2. Visceral sidedness
3. Systemic and pulmonary venous connections
4. Atrial sidedness and their connections
5. Atrioventricular (AV) valves
6. Ventricle sidedness
7. Ventriculoarterial connections
8. Great vessel number and position

The description of cardiac position in the chest can be separated into where the heart is located and the direction in which the apex of the heart is pointed. Normally, the heart is in the left chest with the apex pointed to the left. Dextro- (right) or meso- (midline) position of the heart can occur with decreased right lung volume, severe scoliosis, or an elevated left diaphragm. Typically, the position of the heart in the chest is determined by a chest X-ray. The normal leftward-pointing apex of the heart (levocardia) can vary to mesocardia (in various heterotaxy syndromes) or dextrocardia (in situs inversus). The orientation of the apex of the heart is usually defined by echocardiography.

Visceral sidedness is often defined separately for the abdominal organs, the cardiac structures, and the lungs, although they frequently follow one another. Sidedness is referred to solitus (normal), inversus (mirror image), or ambiguus (isomerism or indeterminate). In the latter situation, effort is made to define whether the organs that appear on both sides are right-sided (liver, right atrium, and trilobed lung) or left-sided (stomach/spleen, left atrium, bilobed lung) structures since this can have prognostic and therapeutic importance. For instance, patients with bilateral right-sidedness typically lack a spleen and require lifelong prophylactic antibiotics for encapsulated organisms and have malrotation of the intestine.

Venous connections of the superior and inferior venous systems must also be delineated. The usual connection of the SVC to the right atrium may also be accompanied by a persistent left SVC to the coronary sinus, with or without a bridging brachiocephalic vein. The IVC is derived from various embryologic vessels and can have its suprahepatic segment interrupted, in which case the normal connection of the IVC to the right atrium does not occur. In this case, lower extremity blood flow is routed to the SVC through the azygous or hemiazygous systems. Various pulmonary venous connections are described below.

Atria can be solitus with the morphologic right atrium on the right (normal), inversus, mirror image, common, or, rarely, indeterminate. The right atrium is typically identified by its venous connections (in particular, the coronary sinus), the presence of the crista terminalis, the large sail-shaped appendage, and the coarse pectinate muscles of the free wall. The left atrium is characterized by its smooth walls and narrow, finger-shaped appendage. Atrial morphology can typically be discerned by echocardiography, although angiography may also aid in their distinction. When the morphologic right atrium connects to the morphologic right ventricle (and similarly on the left), the connection is *concordant*. A *discordant* connection occurs when the morphologic right atrium connects to the morphologic left ventricle as in corrected transposition of the great arteries (TGA). When both atria connect to one ventricle (as in double inlet left ventricle) or a single ventricle, the type of connection is referred to as *univentricular*. An *ambiguous* connection occurs in cases of atrial isomerism.

The AV valves usually travel with their ventricle. As such, the tricuspid valve, when present, connects to the morphologic right ventricle, and the mitral valve connects to the morphologic left ventricle. The tricuspid valve has three leaflets and is distinguished from the mitral valve by the septal attachments of its papillary muscles and the slight inferior position of the septal leaflet of the tricuspid valve relative to the anterior leaflet of the mitral valve. When the AV valves fail to undergo septation, a common AV valve is found as in children with a complete AV septal defect. The position of the AV valves and their chordal attachments are used to define whether the valves are *malaligned* or *straddling*. A malaligned AV valve is not completely positioned over its respective ventricle, which is sometimes referred to as *overriding*. If the chordal attachments of an AV valve cross the septum and connect to the other ventricle, an AV valve is referred to as *straddling*.

The morphology of the ventricles, the associated AV valve, and the outflow portion of the ventricle can generally be used to identify the right and left ventricles. The right ventricle, besides being associated with the tricuspid valve, is more heavily trabeculated at its apex and anterior free wall than the left ventricle. In addition, an infundibular or conus ring exists in the right ventricle that separates the tricuspid and semilunar valves. The left ventricle, besides being more smooth walled with finer trabeculations at its apex than the right ventricle, demonstrates fibrous continuity

between the mitral and semilunar valves. When the ventricular morphology is uncertain, the ventricles are said to be *indeterminate*. A *common ventricle* is defined by virtual absence of the interventricular septum.

The great vessels are largely defined by their branching pattern. The pulmonary artery bifurcates shortly after exiting the heart into the right and left pulmonary arteries that undergo subsequent branching to supply the segments of the lung. The right pulmonary artery is positioned anterior to the right upper bronchus while the left pulmonary artery is posterior to the left upper bronchus. The pulmonary arteries typically follow the situs of the lungs such that mirror image pulmonary artery branching is seen in situs inversus, bilateral branch pulmonary arteries anterior to the upper bronchus are seen in right isomerism, and branch pulmonary arteries posterior to the upper bronchus are seen in left isomerism. The aorta is normally left sided, traveling to the left of the main bronchus, and gives rise to the three arch vessels. A right aortic arch passes to the right of the main bronchus before crossing back to the left side of the spine in the thorax and gives rise to mirror image arch vessels such that the first arch vessel, the brachiocephalic artery, bifurcates to give rise to the right subclavian and right carotid. While the aorta is typically posterior and rightward to the main pulmonary artery, the relative position of the vessels can vary greatly. Most commonly, in D-TGA, the aorta is anterior and rightward to the main pulmonary artery. In situations where only a single semilunar valve is present, a truncus arteriosus (or common truncal artery) is found that gives rise to both the aorta and pulmonary artery.

The ventriculoarterial connections are said to be *concordant* when the right ventricle connects to the pulmonary artery and the left ventricle gives rise to the aorta. The ventriculoarterial connection is *discordant* when the opposite occurs. The ventriculoarterial connection can also be *double*, *single*, or *common*. If both great arteries arise from one ventricle, a double outlet occurs. The definition of a double outlet connection is somewhat controversial. For example, in the case of double outlet right ventricle (DORV) with normally related great vessels, some clinicians have proposed basing the definition on whether greater than 50% of the aorta overrides the right ventricle, while others define the double outlet on whether a subaortic conus exists that results in mitral–aortic discontinuity. From a patient management perspective, both situations are relevant for either placement of the ventricular septal defect (VSD) patch or the potential for development of subaortic obstruction, respectively. A single outlet occurs when severe pulmonary hypoplasia occurs such that no main pulmonary artery segment is present. A common outlet occurs in truncus arteriosus.

Clinical Evaluation of the Newborn

Even with the technologic advances in prenatal and postnatal echocardiography and genetic testing, a careful history and physical examination are needed in every newborn with suspected CHD. Birth history, including complications during pregnancy, labor, and delivery, is important to document. Often the child with cyanosis because of structural heart disease has an unremarkable birth history. A difficult labor or delivery may point toward noncardiac causes of cyanosis such as persistent fetal circulation, infection, or pneumothorax. For the child with poor systemic perfusion, a history of premature rupture of membranes or maternal fever may suggest sepsis as a cause for the diminished cardiac function. Hematologic abnormalities that may cause cardiovascular dysfunction in the neonate, such as polycythemia or anemia, may

be suggested by a history of placental abruption or twin–twin transfusion.

Family history is critical to review with the biologic parents. There is a genetic basis for a growing number of congenital heart defects (see later). A sibling with CHD more than doubles the likelihood of future children having CHD (Nora and Nora, 1988). A history of CHD in either of the parents also increases the chance of developing a congenital heart lesion (Nora and Nora, 1987; Whittemore et al., 1994).

Physical examination of the newborn should initially include a general assessment looking for dysmorphic features and the degree of distress of the infant. The child with cardiac obstructive physiology may have shallow, rapid respirations with intercostal and suprasternal retractions. Cyanosis may or may not be seen depending on the degree of hemoglobin desaturation (roughly 5 g of hemoglobin must be desaturated to be clinically evident). Vital signs, including four extremity blood pressures, should be determined along with preductal and postductal oxygen saturation measurement. Palpation of the precordium may identify an overactive or displaced cardiac impulse or the sensation of a thrill caused by turbulent flow. Palpation of the abdomen for a liver edge or spleen tip can often provide an indication of volume overload or neonatal infection. Assessment of femoral and upper extremity pulses is essential. Simultaneous palpation of the right branchial and right femoral pulses allows assessment of comparable timing and intensity of the pulsations. Perfusion and capillary refill of the extremities are also important to determine.

Auscultation is often challenging in the sick neonate. However, characterizing the presence, timing, intensity, position, and radiation of murmurs that are present may provide a clue to the underlying diagnosis. In the tachypneic and tachycardic child, it is critical to listen over the head and liver for a continuous murmur that may indicate an arteriovenous malformation (AVF). The presence of a click or gallop over the precordium may indicate valvar disease or cardiac failure. Assessment of the second heart sound is particularly important. It has been suggested that the presence of physiologic splitting of the second heart sound nearly always suggests a structurally normal heart (El-Segaier et al., 2007).

Signs of CHF in the newborn may be subtle and include resting tachypnea (with no periodic variation), sinus tachycardia, and enlarged liver. Tachypnea may be accompanied by nasal flaring and intercostal and subcostal retractions, particularly in situations where elevated pulmonary venous pressures are present. Grunting respirations are a particularly concerning sign in a newborn and often accompany severe heart failure and decreased systemic perfusion.

Because many infants with CHD are asymptomatic in the newborn period and have a normal physical examination and because routine prenatal ultrasound does not detect all defects, it has been recommended that pulse oximetry screening should be added to the routine newborn screening panel (Mahle et al., 2012). The screen specifically targets critical congenital heart defects or those that usually require an intervention in the first month of life and can lead to death or significant morbidity if not diagnosed in a timely manner. Since this recommendation, there have been several studies focusing on the feasibility, implementation, and impact of the screen (Garg et al., 2013).

Laboratory Assessment of the Neonate

As mentioned previously, initial laboratory assessment should include measurement of preductal (right hand) and postductal (foot) oxygen

TABLE 55.1 Age-Dependent Standards

| Age Group | QRS axis | PRI | QRSD | QV6 (mm) | RV1 (mm) | SV1 (mm) | RV6 (mm) | SV6 (mm) | SV1 + RV6 |
|-----------|----------|-----------|-------------|----------|----------|----------|----------|----------|-----------|
| <1 day | 59–163 | 0.08–0.16 | 0.031–0.075 | 2 | 5–26 | 0–23 | 0–11 | 0–9.5 | 28 |

| 12–15 yr | 11–130 | 0.09–0.18 | 0.044–0.087 | 3 | 0–10 | 0.3–21 | 6.5–23 | 0–4 | 41 |
| Adult | –30–90 | 0.12–0.2 | 0.05–0.1 | | 0–10 | 0.5–23 | 4–23 | 0–4 | 35 |

saturations. Values less than 93% are considered abnormal. The *oxygen challenge test* is performed by increasing the inspired oxygen concentration to 100% for at least 5 minutes. Oxygen saturation values that increase into the normal range may be useful to distinguish an admixture cyanotic heart lesion from lung disease, although this test does not discriminate perfectly. History and physical examination should be included and guide the need for further evaluation. A decrease in postductal oxygen saturations compared with preductal values suggests right-to-left shunting because of an increase in PVR. The unusual situation in which the preductal saturation reading is less than the postductal reading occurs when TGA is combined with pulmonary hypertension and a patent ductus arteriosus (PDA).

An electrocardiogram (ECG) should be obtained in the initial evaluation of the newborn with suspected CHD, although, in the absence of an arrhythmia, it rarely provides a specific diagnosis. The neonatal ECG demonstrates prominent rightward forces and may have an upright T wave in the right precordial leads in the first few days after birth and thus may not be diagnostic of right ventricular hypertrophy. Age-dependent standards are available and should be referred to when evaluating the ECG (Table 55.1). Certain lesions may have distinctive findings on ECG such as extreme right axis deviation and Q waves in leads I and aVL (complete AV canal), preexcitation and right atrial enlargement (Ebstein anomaly), and Q waves in leads V1–V3 (corrected TGA).

A chest X-ray should also be obtained in every newborn that is evaluated for CHD. The chest X-ray may help to determine if lung disease is contributing to cyanosis. The heart size, shape, and border contours should be evaluated on the chest X-ray along with pulmonary vascular markings. A prominent thymic shadow in the newborn may make identification of classic chest X-ray findings difficult (such as the “boot-shaped” heart in tetralogy of Fallot (TOF), the “egg on a string” in transposition, and the “snowman” appearance in supracardiac total anomalous pulmonary venous return (TAPVR) although the massively increased heart size typically

found with Ebstein anomaly will not be missed. An absent thymic shadow may suggest DiGeorge syndrome (22q11 deletion), although genetic testing is still required. Increases in pulmonary vascular markings typically found in left-to-right shunt lesions may not be immediately apparent in the newborn because of the relatively high PVR and may take days or weeks to become apparent. Often, decreased pulmonary vascular markings in lesions with diminished pulmonary blood flow, such as tricuspid or pulmonary atresia, will be apparent in the newborn period. Presence of a PDA, however, will improve pulmonary blood flow in these lesions.

Echocardiography is truly the mainstay in the diagnosis of CHD in the neonate (described in detail in Chapter 53). While we encourage complete cardiovascular evaluation and consultation with a pediatric cardiologist in all children with suspected CHD, more programs are performing echocardiograms in neonates without the direct evaluation of the newborn by a pediatric cardiologist. In these instances, it is critical to have the echocardiographic examination reviewed by a pediatric cardiologist with some knowledge of the clinical condition of the child. Further, the pediatric cardiologist reading the echocardiogram should discuss the findings directly with the caregivers in order for the team to define relevant therapy and follow-up.

Genetics and Congenital Heart Disease

Our understanding of the genetic basis of CHD is progressing at a rapid pace. The early identification of the association of specific syndromes with CHD suggested that it would be possible to identify genes relevant to abnormal cardiac morphogenesis. With the completion of the Human Genome Project and the availability of large scale sequencing techniques, genetic causes for CHD continue to become more highly refined. For example, copy number variants, a term used to reflect the quantity of genes expressed when large segments of DNA are amplified or deleted, contribute to the syndromic CHD found in DiGeorge syndrome where a 3 megabase

disruption occurs at 22q11. A variety of copy number variants contributing to both syndromic and nonsyndromic CHD disease have been identified (Fahed et al., 2013).

The list of point mutations that cause a particular CHD continues to grow as individuals and families are studied using next-generation sequencing. Considerable postprocessing of the sequence data is needed to exclude common polymorphisms in the sequence. Syndromic CHD found in Alagille syndrome, Noonan syndrome, and Holt–Oram syndrome has been linked to point mutations. The list of nonsyndromic point mutations causing isolated CHD continues to grow (Allen et al., 2008; Fahed et al., 2013).

Despite these advances in the understanding of the genetic basis of CHD, the genetic basis of more than half of children with CHD is not known. It is likely that altered interactions with noncoding regions of the genome impact the degree to which genes that regulate cardiac development are expressed. There may also be gene–environment interactions, yet to be defined, which impact cardiac development.

A child with suspected CHD should be carefully evaluated for dysmorphic features that may indicate an associated syndrome. The converse is also true in that if a newborn is suspected to have a syndrome, careful cardiac evaluation, including an echocardiogram, should be considered.

Screening chromosomes are an important initial step in the genetic evaluation of the newborn with a presumed syndrome. Well-described associations of congenital cardiac lesions with chromosome abnormalities include trisomy 21 with complete AV septal defect, Turner syndrome (45 XO) with coarctation of the aorta, William syndrome (7q11 deletion) with valvar and supravalvar pulmonic stenosis, and DiGeorge or velocraniofacial syndrome (22q11 deletion) with conotruncal anomalies. These syndromes, and others, make karyotype analysis with fluorescent in situ hybridization (FISH) analysis an important initial step in the work-up of infants with these lesions.

Genetic testing should be performed in all newborns with suspected syndromes whether or not CHD is present. FISH studies for 22q11 deletions should be performed in all infants with conotruncal anomalies such as TOF, truncus arteriosus, and interrupted aortic arch. Other FISH studies can be specifically ordered at most institutions although the maximum number of fluorescent probes is typically four or five due to detection limitations of the range of wavelengths available. Genome-wide chromosome microarray screening is now also available that can detect deletions and duplications across the genome.

Genetic testing is not only useful to help provide prognostic information for a specific patient but also to provide counseling for the family. Referral to a consulting genetics faculty should be considered whenever a karyotype, FISH study, or genome-wide chromosome microarray is found to be abnormal. Consideration of services available to the infant, screening of additional family members, and risk to future pregnancies will be reviewed during the genetics consultation that will impact on the overall care of the patient.

Heart Transplantation

Surgical palliation for congenital heart lesions allows most structural abnormalities in the newborn period to be corrected or palliated. In instances where the abnormality is primarily myocardial or surgical repair has not sufficiently corrected the child's hemodynamics, cardiac transplantation may be the only therapeutic option.

The first heart transplant in an infant was reported in 1968 (Kantrowitz et al., 1968). Since then, understanding of transplant immunology and medical management has made heart transplant in infants and children an important option for inoperable patients or those with end-stage cardiac disease. In a recent scientific statement from the American Heart Association (Canter et al., 2007), the indications for pediatric heart transplant were defined (adapted from Canter et al., 2007):

1. Need for ongoing intravenous inotropic or mechanical circulatory support
2. Complex CHD not amenable to conventional surgical repair or palliation or for which the surgical procedure carries a higher risk of mortality than transplantation
3. Progressive deterioration of ventricular function or functional status despite optimal medical care
4. Malignant arrhythmia or survival of cardiac arrest unresponsive to medical therapy, catheter ablation, or an automatic implantable defibrillator
5. Progressive pulmonary hypertension that could preclude future transplantation
6. Growth failure secondary to severe CHF unresponsive to conventional medical therapy
7. Unacceptably poor quality of life

There are a variety of lesions in the neonate for which cardiac transplantation has been used as primary palliation. These have included hypoplastic left heart, pulmonary atresia with intact ventricular septum and presence of coronary sinusoids, complex heterotaxy or unbalanced complete AV canal with poor common AV valve function, and single ventricle hearts where the dominant semilunar valve is severely insufficient. When considering transplantation in these patients, there is a balance between the success of palliative surgery and the availability of organs for transplantation. For example, over the past decade, survival of patients undergoing surgical palliation of hypoplastic left heart syndrome (HLHS) has continued to improve (Alsoufi et al., 2007a; Gordon et al., 2008). With the availability of infant donors increasing only slightly over this period of time (Table 55.2), the balance for treatment of these newborns has shifted toward surgical palliation with the Norwood or hybrid Norwood procedures.

Patients with the other lesions noted in this section continue to have relatively poor surgical outcomes, suggesting that palliation with heart transplantation may be the best approach. Given the limited availability of organs, however, it should be recognized that some of these infants will not survive to transplant (Kirklin et al., 2006). The long-term survival of infants who undergo heart transplantation is quite good. The 10-year survival in infants continues to improve, with current survival rates of 66% (Boucek et al., 2007). It is interesting that there appears to be a survival advantage in children who receive their transplant prior to 1 month of age versus those between 1 and 12 months (del Rio, 2000). While the mechanism of the improved survival in the younger neonates is not known,

TABLE 55.2 Number of Available Donors for Infant Heart Transplant by Year in the United States

| Year | 2006 | 2007 | 2008 | 2009 | 2010 | 2011 | 2012 | 2013 | 2014 | 2015 |
|--------|------|------|------|------|------|------|------|------|------|------|
| Donors | 89 | 87 | 100 | 116 | 105 | 110 | 106 | 117 | 120 | 126 |

Data from the Organ Procurement and Transplant Network Database (<http://optn.transplant.hrsa.gov>)

it may reflect an immunologic window where graft rejection and transplant coronary artery disease are limited.

Ventricular Assist Devices

Over the past several years, mechanical circulatory support devices have increasingly been developed for the pediatric population to serve as a bridge for postoperative cardiac recovery or heart transplantation. While the availability of devices for neonates lags far behind older children and adults, options are now available.

The mechanical circulatory support device approved for use in children is the Berlin Heart EXCOR pediatric ventricular assist device (VAD). This is a pneumatically driven device that comes in five sizes, with the smallest of the devices delivering a volume of 10 mL per stroke. One or two devices can be implanted to support one or both ventricles, respectively. Studies have looked at survival and complications in infants in the 3–5 kg range and a corrected gestational age of at least 37 weeks of age, in comparison with older children (Almond et al., 2013). Early mortality was increased in association with lower body weight. In the 33 infants included in the study who were less than 5 kg, 64% died following VAD implantation.

Given the challenges of the use of current VADs in infants, other devices continue to be developed (Baldwin et al., 2011; Vanderpluym et al., 2014) and are either in the experimental stage or available for compassionate use. The development of these smaller devices has been supported, in part, by the Pediatric Circulatory Support Program of the National Heart, Lung, and Blood Institute. Several devices are in various stage of testing (Baldwin et al., 2011), some of which are small enough in size for use in infants.

Murmurs in the Newborn—Congenital Cardiac Lesions

Patent Ductus Arteriosus and Aortopulmonary Window

As discussed earlier, virtually every child is born with a PDA that typically closes within the first week of life. Prematurity is a risk factor for a persistent PDA and is covered in Chapter 54. Persistent PDA in term infants occurs more commonly in females and may have a genetic component in some patients, as suggested by an animal model of inbred poodles (Knight et al., 1973) and linkage to chromosome 12 (Mani et al., 2002).

The pathophysiology of a PDA largely depends on the degree of shunting from the aorta to the pulmonary artery, which is determined by the inner diameter and length of the PDA and the relative pulmonary and systemic resistances. If the PDA diameter is small, the ductus itself will provide the primary site of resistance to flow, and the shunt will be small. In the case of a larger PDA, low PVR may allow for a significant shunt that places the patient at risk for developing heart failure and, eventually, pulmonary vascular occlusive disease. The low resistance pathway through the lungs provides a route for diastolic run-off from the aorta that can result in decreased coronary perfusion pressure. The diastolic steal by the pulmonary artery can lead to myocardial ischemia.

Clinically, patients with a small shunt will be asymptomatic. With a larger PDA shunt, the progressive decline in PVR postnatally will cause an increase in left-to-right shunt flow with signs of increasing heart failure. The murmur in a child with a PDA is generally continuous and has been described as a “machinery”

murmur in the left infraclavicular region. The character of the murmur, however, varies greatly, although the continuous nature is generally present once the PVR has declined. Examination of the patient with a PDA will also include a wide pulse pressure because of decreased diastolic pressure and bounding pulses.

The diagnosis of PDA, when suspected on examination, can nearly always be confirmed by echocardiography. Even in the face of high PVR with limited left-to-right shunting, differences in the pulse waveforms between the aorta and pulmonary artery will allow left-to-right and/or right-to-left shunting to be observed by color Doppler imaging. Echocardiography can also provide information regarding the degree of left-to-right shunting, as the dimensions of the left atrium and left ventricle are increased and the left atrium-to-aorta ratio is increased. In addition, retrograde flow will be seen in the proximal descending aorta when a large shunt is present. Cardiac catheterization is rarely needed unless coil closure of the PDA is considered.

The prognosis for small PDAs is quite good, and debate exists as to whether closure of “silent” PDAs, incidentally identified by echocardiography, should be performed (Giroud and Jacobs, 2007). With the most recent recommendations from the American Heart Association suggesting that PDAs do not require subacute bacterial endocarditis prophylaxis (Wilson et al., 2007), there is little need to close these small vessels.

Because of the long-term concerns of pulmonary overcirculation and the development of pulmonary vascular occlusive disease, closure of PDAs by 1 year of age is recommended when a significant left-to-right shunt is present. Surgical ligation and division can readily be performed through a lateral thoracotomy. However, coil or device closure in the catheterization lab has a lower morbidity and success rates equal to surgery (Arora, 2005). As a result, catheter closure of PDAs has become the preferred method in nonpremature infants. Success of device closure depends in part on the weight of the infant and size and shape of the PDA. With the current array of devices available, closure can be safely performed in most infants weighing more than 4 kg and can be considered in some infants weighing between 2.5 and 4 kg (Brunetti et al., 2010; Dimas et al., 2010).

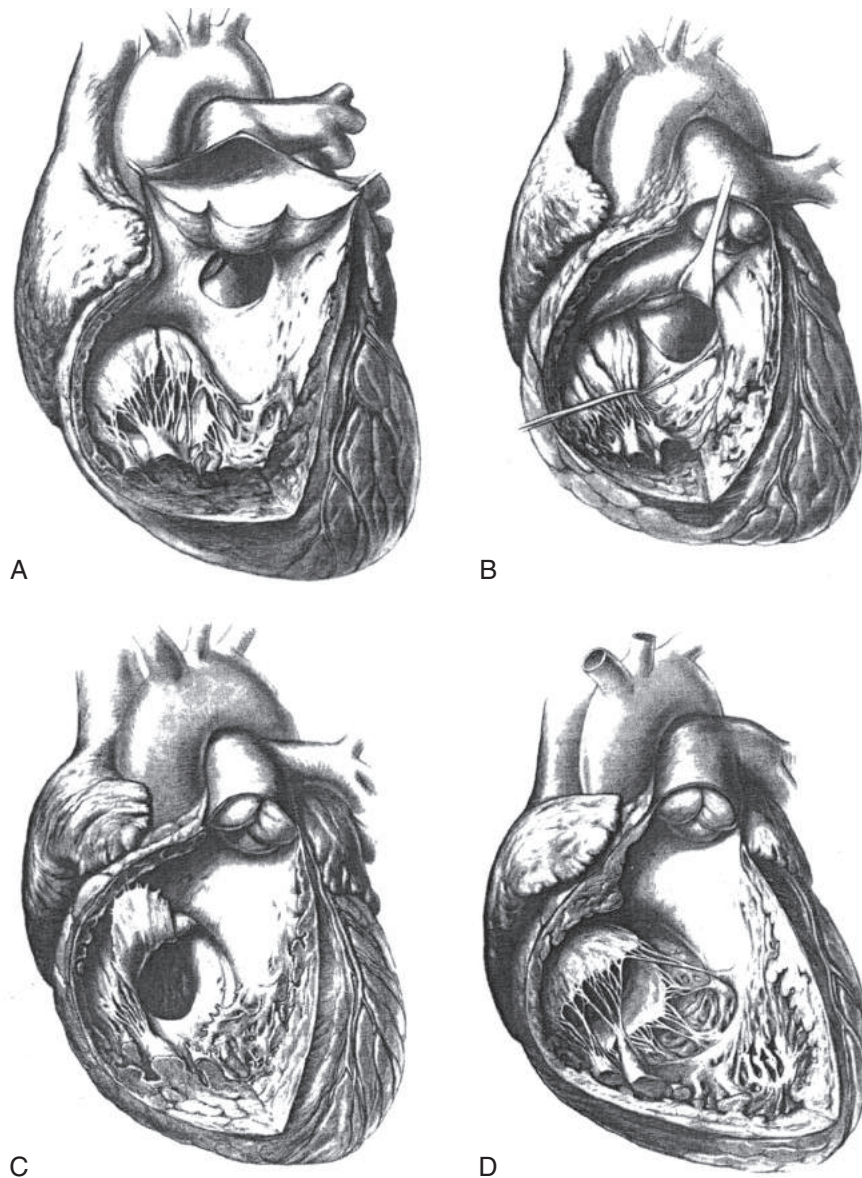

Aortopulmonary (AP) window occurs when there is direct communication between the aorta and main pulmonary artery and is a rare lesion that can readily be confused with PDA on both physical and laboratory evaluation. Nearly half of patients with an AP window will have an associated cardiac anomaly. These lesions nearly always result in a large degree of left-to-right shunting. Patients will show signs of CHF on examination and have physical and laboratory findings similar to those for a large PDA. Generally, all AP windows should be closed when they are identified. Closure of an AP window must be done surgically, generally with patch closure from the pulmonary artery side being the preferred technique.

Ventricular Septal Defect

VSDs are the most common type of CHD (excluding bicuspid aortic valve). Generally, VSDs are classified into four types (Fig. 55.2):

1. Perimembranous
2. Muscular
3. Inlet
4. Outlet

The perimembranous VSD is the most common of the four types and has variably been referred to as membranous, paramembranous, or infracristal. From the right ventricular side of the heart, these defects lie under the septal leaflet of the tricuspid valve below the

• **Fig. 55.2** Anatomic Varieties of Ventricular Septal Defect. (A) Subpulmonary defect. (B) Membranous defect. (C) Inlet (atrioventricular septal defect type) defect. (D) Apical muscular defects. (From Mavroudis C, Backer CL. *Pediatric Cardiac Surgery*. St. Louis, MO: Mosby Year Book; 1994.)

crista supraventricularis and posterior to the papillary muscle of the conus. Muscular VSDs can occur in isolation or as multiples (“Swiss cheese septum”) and, as the name implies, can occur anywhere in the muscular septum. Apical muscular VSDs are the most common and are sometimes difficult to accurately size by echocardiography because of the heavy trabeculations at the apex of the right ventricle. Inlet VSDs are located posterior and inferior to perimembranous defects, and, although the nomenclature is controversial, this is the location of the defect in patients with complete atrioventricular septal defects. The location of the VSD in patients with outlet defects is above the crista supraventricularis and typically undermines the right aortic valve leaflet. A variety of synonyms have been used for outlet VSDs including subarterial, subaortic, supracristal, and conal VSD.

The clinical importance of any VSD is dependent upon the size of the defect and the relative pulmonary-to-systemic vascular resistance, which together determine the degree of left-to-right shunting. An

additional consideration with outlet VSDs is the degree to which the right coronary cusp of the aortic valve prolapses into the defect and results in aortic insufficiency. Defects whose cross-sectional area is equal to, or greater than, the cross-sectional area of the aortic valve will not restrict flow leaving the left ventricle and entering the right ventricle. In this case, the degree of shunting will be determined by the relative resistance to flow in the pulmonary and systemic vascular beds. The normal postnatal decline in PVR will result in a progressive increase in left-to-right shunting and signs of CHF. A small percentage of children do not have the usual postnatal decline in PVR and may never develop signs of pulmonary overcirculation and heart failure despite the presence of a large VSD. This is an indication for early surgical closure of the defect.

When the VSD is small relative to the aortic valve, the defect itself will be the primary point of resistance to shunt flow. In this case, changes in PVR will have little impact on the degree of left-to-right shunting.

An important associated lesion that is critical to rule out is coarctation of the aorta. The coarctation results in a fixed elevated systemic vascular resistance that can result in important left-to-right shunting even in the presence of a small VSD. In this case, medical therapy is often unable to control CHF symptoms, and surgery is needed.

The volume of shunted blood is most accurately quantitated at cardiac catheterization based on the step-up in oxygen saturation from the right atrium (mixed venous) to the pulmonary artery and is represented as the ratio of pulmonary-to-systemic blood flow ($Q_p : Q_s$). Generally, a $Q_p : Q_s$ less than 1.5 is considered below the threshold for surgery, while a $Q_p : Q_s$ greater than 2.0 is an indication for surgery. The $Q_p : Q_s$ can also be estimated by echocardiography and by magnetic resonance imaging (MRI).

The examination of the patient with a VSD depends on the magnitude of the shunt. Small defects that provide considerable restriction to flow often have the loudest murmur. The rapid drop in PVR immediately after birth often allows VSD murmurs to be heard in the newborn nursery, although the full extent of the murmur, and perhaps a thrill at the lower left sternal border, may not be appreciated for several weeks. The murmur may have a more ejection quality in the newborn nursery in the face of high PVR and somewhat elevated right ventricular pressure. The more typical holosystolic murmur will be more apparent as the PVR falls.

With large VSDs, little or no murmur may be heard depending on the PVR. With low PVR, signs of heart failure will likely be present including tachypnea with nasal flaring and retractions, tachycardia, diaphoresis, poor feeding, and diminished weight gain. A systolic murmur at the lower left sternal border (caused by flow across the VSD) or upper left sternal border (caused by increased flow across the right ventricular outflow tract [RVOT]) may be heard along with a diastolic inflow rumble (an absence of silence) at the apex. If PVR is high, the pulmonic component of the second heart sound may be increased although difficult to appreciate. Occasionally, large defects may allow transient right-to-left shunting to occur, particularly when the infant is crying.

In patients with an outlet VSD, the holosystolic murmur is often present, but the murmur is located higher on the left sternal border. Care should be taken to listen for the diastolic decrescendo of aortic insufficiency at the mid-left sternal border or at the apex.

The laboratory evaluation of the infant with a suspected VSD should include an ECG, chest X-ray, and echocardiogram. In infants, the ECG may not be distinctive unless an inlet VSD is present. Obtaining a chest X-ray, even in the neonate, is important in order to assess heart size and pulmonary vascular markings. It can also be an important tool in the follow-up of newborns with VSDs when used to assess progression in left-to-right shunting as the PVR declines. Echocardiography is the gold standard for characterizing the location and size of VSDs. Associated lesions, such as coarctation of the aorta, can also be readily assessed by echocardiography. Doppler studies can estimate the degree of restriction by calculating the pressure drop at the defect (see Chapter 53). M-mode measurements can be used to determine left ventricular dimensions, which will be increased when a significant left-to-right shunt is present. As mentioned above, cardiac catheterization can accurately quantitate the degree of shunting but is rarely needed in the initial assessment of the newborn with VSD.

Up to 80% of small, muscular VSDs and 30%–50% of perimembranous defects will close spontaneously. It is uncommon for these defects to increase in size although the degree of left-to-right shunting can increase as PVR drops. Occasionally, inlet VSDs will undergo closure secondary to chordal attachments of the AV valves,

but closure is generally present at birth if it is going to occur. Outlet VSDs virtually never close and have the associated risk of progressive aortic insufficiency because of prolapse of the right coronary cusp into the defect.

The short-term consideration in following patients with VSDs is the management of CHF if the left-to-right shunt is excessive. Medications that are used include furosemide (typically 1 mg/kg per dose b.i.d [twice daily]), digoxin (5 mcg/kg per dose b.i.d), and afterload reduction with enalapril (initial dose of 0.05 mg/kg per dose b.i.d, up to 0.2 mg/kg per dose b.i.d, when monitoring blood pressure). The primary goal in controlling CHF is to allow the newborn to grow adequately and hopefully allow progressive closure of the VSDs. Weight gain is a useful and objective measure to follow.

The long-term goal of therapy or intervention is to prevent the development of irreversible pulmonary vascular occlusive disease. Shunts with a $Q_p : Q_s$ greater than 2.0 are at long-term risk of developing Eisenmenger disease, and closure of the defect is warranted beyond 2–4 years of age when further decline in defect size is unlikely.

If medical therapy fails to control heart failure and the infant exhibits failure to thrive, surgical closure of the defect in the first 6 months of life is required. Surgical closure is also indicated in the 6–12-month-old child with a large VSD who has not demonstrated signs and symptoms of CHF due to lack of decline in PVR. In these infants, irreversible changes in the pulmonary vasculature may occur if the pressure load is not taken off the lungs. As mentioned previously, defects with a $Q_p : Q_s$ greater than 2.0 and outlet defects also require closure. The use of pulmonary artery banding is falling out of favor for palliation of patients with VSDs unless the patient's clinical condition makes complete repair untenable. There is growing use of hybrid procedures where the surgeon and interventional cardiologist work together to close defects in small children (Contrafouris et al., 2009). This combined approach has successfully been applied to the closure of muscular VSDs in infants that are positioned in a location that is difficult for the surgeon to visualize from a right atrial approach. Additional indications for the hybrid approach to VSD closure will likely be determined in the coming years.

Atrial Septal Defects

Although atrial septal defects (ASDs) rarely produce a murmur in the neonatal period, the systolic murmur they generate later in life makes them appropriate for this section. As discussed earlier, atrial level shunting through the foramen ovale in utero allows the nutrient-rich placental blood to gain access to the left ventricle and ascending aorta. In the immediate postnatal period, careful echocardiography examination of the interatrial septum will usually identify residual left-to-right or bidirectional shunting through the foramen ovale. Measurement of the size of the shunt provides an indication of whether there will be a persistent septal defect. An opening less than 6 mm in a term infant will most likely close and is referred to as a patent foramen ovale (PFO) to distinguish it from a true ASD. ASDs that represent congenital lesions are classified as:

1. Secundum
2. Primum
3. Sinus venosus
4. Coronary sinus

Secundum defects are the most common and, when present in the neonate, allow for left-to-right or bidirectional shunting. The

direction of the shunt, and the reason an ASD murmur is typically not heard in the neonate, is that right ventricular compliance remains low until the RV remodels postnatally. The reduced RV compliance increases right atrial pressure and limits the amount of left-to-right atrial level shunting. Secundum ASDs are associated with Holt–Oram syndrome (abnormal radii, first degree AV block, and ASD). Primum ASDs are in the spectrum of atrioventricular septal defects and will be considered in the next section. Sinus venosus defects occur when the wall separating the upper or lower right pulmonary vein is deficient so that pulmonary venous return from either or both veins spills into the right atrium. This results in a left-to-right shunt. This variant of anomalous pulmonary venous return will be considered in greater detail further in the chapter. Coronary sinus defects result from an “unroofing” of the coronary sinus so that the coronary sinus enters at the left atrium–right atrium junction where the septum is deficient. Often, this lesion is associated with a persistent left SVC that enters into the coronary sinus.

In later childhood, when the compliance of the right ventricle increases and left-to-right shunting through an ASD increases, the classic physical findings of fixed splitting of the second heart sound. A systolic ejection murmur at the left upper sternal border, and a diastolic right ventricular inflow murmur at the lower left sternal border become apparent in lesions with a $Q_p : Q_s$ more than 2.0. ECG will often demonstrate an rsR' pattern in the right precordial leads with evidence of right ventricular hypertrophy. Cardiomegaly with a prominent main pulmonary artery segment and increased vascular markings will be seen on chest X-ray. Echocardiogram remains the gold standard for identifying and sizing the defects.

It is uncommon for infants and children with an isolated ASD to develop heart failure. Typically, intervention for a significant ASD is performed to prevent the long-term sequelae of pulmonary vascular occlusive disease. As such, closure is rarely performed before the age of 3 or 4 years. Device closure of secundum ASDs is now routinely performed in the catheterization lab when children are greater than 15 kg, although surgical closure is still performed when lesions are large or the rim of tissue between the ASD and aorta is deficient.

Atrioventricular Septal Defects

A variety of terms have been used to describe AV septal defects including AV canal defect, endocardial cushion defect, and common AV orifice. In addition, there is a spectrum of AV septal defects:

1. *Complete*—common AV valve is present along with a significant primum ASD and inlet VSD.
2. *Intermediate*—common AV valve annulus although separate AV valves along with a primum ASD and inlet VSD.
3. *Transitional*—completely separate AV valves along with a primum ASD and inlet VSD.
4. *Partial*—separate AV valves with a primum ASD and no VSD.

These four groups have some therapeutic relevance with regard to the degree of AV valve abnormality that must be considered at surgery, although each has a cleft between the anterior bridging leaflet and the lateral leaflet of the left-sided (mitral) valve that must be addressed. In infants with a complete AV septal defect, it is important to assess whether the right and left ventricles are *balanced*, that is, equally developed so that a two-ventricle repair is possible, and the degree of AV insufficiency, which has prognostic importance in the surgical outcome. AV septal defects are common in children with Down syndrome.

In the immediate postnatal period, variations in PVR that occur, particularly in infants with Down syndrome, can result in a right-to-left shunt through a nonrestrictive primum ASD and/or inlet VSD and result in systemic desaturation. Many infants with complete AV septal defects will develop heart failure in the first 2 months of life as PVR falls. A small percentage of infants will not have a decline in PVR, making the lack of heart failure a troubling sign and an indication for early surgical repair.

While diagnosis largely rests on the echocardiogram, AV septal defects can be suspected on ECG with the presence of a superior frontal QRS axis (ranging from -30 to -120 degrees), evidence of right ventricular hypertrophy, and Q waves in leads I and aVL. Echocardiogram is used to define the type of AV septal defect and identify associated anomalies (Fig. 55.3). As mentioned above, critical assessment of relative ventricular sizes and the degree of AV valve insufficiency is necessary. Interrogation of the RVOT is

• **Fig. 55.3** Echocardiographic View of Complete Atrioventricular Septal Defect. (A) Four chamber view showing the common atrioventricular valve that separates the atria and ventricles, which in this patient are well balanced. The large primum atrial septal defect and inlet ventricular septal defect are seen. (B) With color Doppler, inflow across the atrioventricular valve is seen.

also needed due to the associated pulmonic stenosis or TOF that can occur with complete AV septal defects.

Correction of complete AV septal defects is performed surgically at 4–6 months of age. While awaiting surgery, care must be taken not to treat minor desaturation episodes with excessive oxygen since oxygen-induced lowering of PVR can rapidly worsen heart failure and lead to further desaturation, a spiral that can be difficult to reverse. Furosemide, digoxin, and afterload reduction are often needed to control heart failure, and some cardiologists will start these medications in the immediate postnatal period because of the high likelihood of infants developing CHF. Complete repair (septation atria, ventricles, and AV valves) is preferred. It is very rare that palliative banding of the pulmonary artery is needed to control heart failure symptoms. As mentioned above, early repair should be considered in the infant who does not have a decline in PVR and the development of heart failure, because of the concern of early development of irreversible increases in PVR, particularly in non-Down syndrome complete AV septal defect patients.

Peripheral Pulmonic Stenosis

Peripheral pulmonic stenosis (PPS) can range widely in its severity. In many instances, mild narrowing of the branch pulmonary arteries occurs in the neonate and produces a murmur that is heard widely throughout the chest. The murmur caused by this mild PPS is considered by some to be an “innocent murmur” of infancy and usually resolves by 2–4 months of age. This lesion likely reflects mild hypoplasia of the branch pulmonary arteries because of decreased in utero pulmonary blood flow and the postnatal transition where these vessels must accommodate the entire cardiac output following ductal closure.

More severe PPS is seen in cases of congenital rubella syndrome or in association with Williams or Noonan syndrome. Branch pulmonary artery stenoses can also occur with TOF. In these cases, multiple levels of obstruction may exist that require catheterization or surgical intervention.

In isolated or mild PPS, minimal right ventricular pressure overload occurs. With increasing stenosis, right ventricular pressure overload will result in right ventricular hypertrophy and, in later stages, right atrial enlargement on ECG. Echocardiogram can interrogate the proximal pulmonary arteries, but more-distal lesions require other imaging modalities such as MRI or cardiac catheterization.

Intervention to treat severe branch stenoses should be considered when right ventricular pressure is greater than 75% of systemic pressure or any clinical or laboratory evidence of right ventricular dysfunction is present. Surgical management is possible for proximal areas of stenosis, although the treatment preferred by most clinicians is balloon dilation or expandable stent placement in the cardiac catheterization laboratory. Repeated interventions may be needed to enlarge vessels as the patient grows or to dilate other areas of stenosis that develop.

Pulmonic Stenosis

Isolated pulmonary valve stenosis is a common cause of a systolic ejection murmur in the neonatal period. While cases typically occur sporadically, more than 50% of infants with Noonan syndrome will have pulmonic stenosis, and thus the pulmonary valve should be evaluated in all these children.

The degree of pulmonic stenosis determines the pathophysiology of the disease process. As the stenosis of the valve worsens, right

ventricular pressure increases along with the degree of right ventricular wall stress. Right ventricular hypertrophy will develop if the stenosis is left untreated. In severe or critical pulmonic stenosis (discussed later in the section), heart failure can develop in the neonate accompanied by cyanosis due to right-to-left shunting at the atrial level.

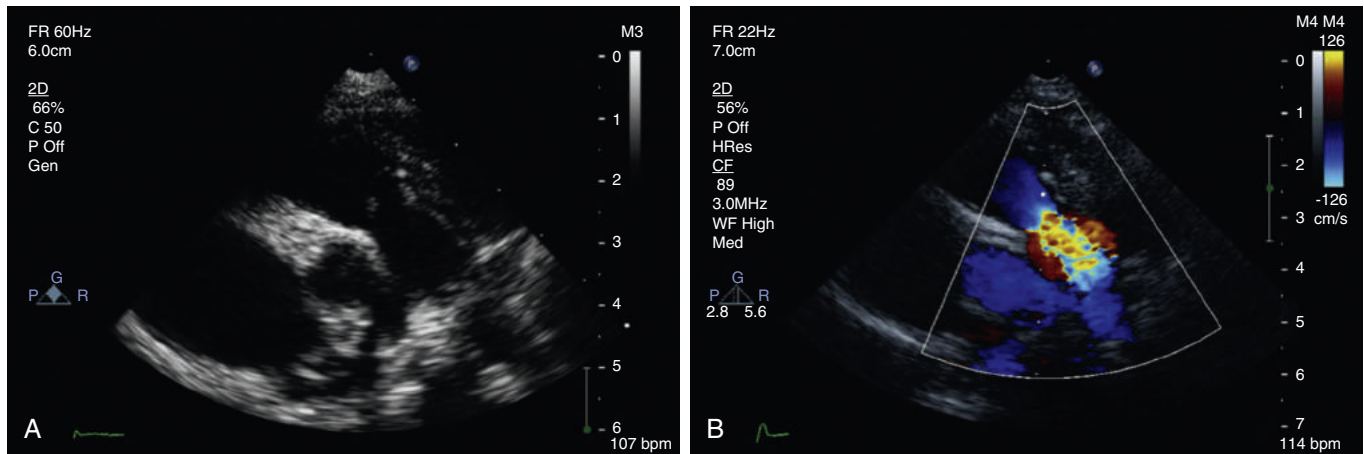

The degree of stenosis is generally classified based on the pressure drop across the pulmonic valve with mild stenosis defined as a gradient less than 30 mmHg, moderate stenosis as a gradient of 30–60 mmHg, and severe stenosis as higher than 60 mmHg. While these definitions were initially based on cardiac catheterization, current follow-up of patients with pulmonic stenosis utilizes echocardiogram, which overestimates the gradient compared with direct hemodynamic measurement obtained from cardiac catheterization. Thus some use an *echo gradient* of more than 40 mmHg as mild pulmonic stenosis.

Consideration of the valve gradient is critical because of the prognostic significance of the value. In older children, mild stenosis rarely progresses (Nugent et al., 1977). In infants, however, follow-up of patients with echo gradients over 40 mmHg found that 29% developed progressive valve stenosis, with half of those showing an increase in the first 6 months of life (Rowland et al., 1997). Neonates with moderate valve stenosis may face an even greater likelihood of developing progressive stenosis, although limited data exist.

A systolic ejection murmur of pulmonic stenosis can be heard in the neonatal period at the upper left sternal border. Typically, although the fast heart rate in the neonate may make it difficult to appreciate, a systolic ejection click just after the first heart sound (S1) can be heard in most of these infants and is an important feature to distinguish pulmonic stenosis from other lesions. Much like PPS (see earlier), the murmur of pulmonic stenosis radiates throughout the lung fields. As the gradient across the valve worsens, a thrill may be palpable at the upper left sternal border. As the degree of stenosis progresses further and becomes severe, the murmur and click will diminish and may even be absent as right ventricular dysfunction worsens. Of note is that while progressive pulmonic stenosis may be able to be estimated on the basis of the murmur, the clinical condition of the infant may not change appreciably until the degree of stenosis becomes severe.

The findings of laboratory studies in infants with pulmonic stenosis will vary depending on the degree of stenosis. ECG will demonstrate right ventricular hypertrophy in most patients with moderate stenosis, although the study may be normal when mild stenosis is present. Chest X-ray is often normal unless poststenotic dilation of the main pulmonary artery has developed. Echocardiography will be diagnostic. The valve will have varying degrees of dysplasia that is characterized by thickened, poorly mobile leaflets that dome during systole. Turbulence distal to the valve will be seen by color Doppler imaging (Fig. 55.4), while pulse wave Doppler is used to determine the degree of stenosis. As discussed previously, Doppler echo generally gives a value of stenosis that is 20%–30% higher than the peak-to-peak pressure gradient measured as cardiac catheterization.

Treatment of isolated pulmonic stenosis, even in the neonate, can readily be performed by balloon valvotomy in the cardiac catheterization laboratory. The exception may be in infants with Noonan syndrome where the degree of valvar dysplasia may prevent an adequate result, although most will initially attempt a balloon valvotomy before progressing to surgery. Valvotomy should be considered in infants with more than mild stenosis. Mild or moderate pulmonary insufficiency, should it develop after balloon

• **Fig. 55.4** Pulmonic Stenosis. (A) Short-axis view of pulmonic stenosis with a thickened-appearing pulmonic valve. (B) Using color Doppler imaging, turbulence in the main pulmonary artery is seen above the pulmonic valve.

valvotomy, is usually well tolerated. Recurrent stenosis and more significant pulmonic insufficiency are found more often when valvotomy is needed in the neonatal period (Garty et al., 2005).

Aortic Stenosis

Similar to stenosis of the pulmonic valve, aortic valve stenosis can produce a murmur in the neonatal period. However, aortic stenosis is more likely to be progressive than pulmonic stenosis. Levels of obstruction of the left ventricular outflow tract can also occur at the subvalve and supravalue levels. Subvalvar stenosis is rarely diagnosed in the neonatal period but often progresses later in life as a fibromuscular ridge beneath the aortic valve. Supravalar stenosis can present in the newborn period and is often associated with Williams syndrome.

As with pulmonic stenosis, the pathophysiology and physical findings associated with aortic valve stenosis depend on the degree of obstruction. Certainly the most common aortic valve abnormality addressed in the neonatal period is critical aortic stenosis associated with decreased left ventricular function. This medical emergent situation is addressed in detail later. Mild (aortic valve gradient <30 mmHg) and moderate (valve gradient of 30–60 mmHg) aortic valve stenosis is not commonly encountered in the neonatal period. When it is, these milder forms of stenosis are generally associated with a bicuspid aortic valve and tend to progress with age. The rate of change of progression throughout infancy and childhood is quite variable and necessitates frequent follow-up of these patients.

The murmur in the newborn with aortic stenosis may be difficult to localize to the upper right sternal border as in older children. A thrill is usually palpable at the suprasternal notch with even mild aortic valve stenosis, with a precordial thrill felt as the degree of stenosis increases. Usually a click from the stenotic aortic valve is heard at the apex or lower left sternal border.

Electrocardiography may be of limited benefit in the newborn with mild or even moderate aortic valve stenosis, although some degree of left ventricular hypertrophy may be seen. Chest X-ray is of limited benefit in following these patients, with the focus of the diagnostic assessment being the echocardiogram. On echocardiogram, the aortic valve can be characterized. Fused leaflets that are thickened and domed are seen. Pulsed Doppler is used to determine the gradient across the valve while color Doppler imaging can define the presence of aortic insufficiency.

Initial management of moderate aortic valve stenosis is balloon valvotomy in the cardiac catheterization laboratory. The balloon is sized in an effort to limit aortic insufficiency, which is much less well tolerated than insufficiency of the pulmonic valve. If significant aortic valve insufficiency is present or develops, surgical repair or valve replacement is needed. In neonates and infants, the Ross procedure is usually the procedure of choice (Elkins et al., 1994). In this procedure, the pulmonary valve is removed intact from the patient and sewn into the aortic position, and a homograft is placed in the pulmonic position. Interestingly, the pulmonary autograft generally demonstrates good growth and excellent function in the aortic position. While the child will outgrow the pulmonary homograft, replacing it and managing progressive pulmonic stenosis are much easier than addressing the aortic valve.

Cyanosis in the Newborn

Congenital heart defects that present with cyanosis do so because of a right-to-left shunt. The shunt results in mixing of the systemic and pulmonary venous returns that can occur between the atria, ventricles, or great vessels. Defects presenting predominantly with cyanosis can be further subclassified by the amount of associated pulmonary blood flow. If there is no restriction to pulmonary blood flow, cardiac output to the lungs will increase as the normal postnatal drop in PVR occurs. Clinically, this results in tachypnea, poor feeding, hepatomegaly, and pulmonary edema. Much of the neonatal management is aimed at balancing the ratio of systemic to pulmonary blood flow. Defects with restriction to pulmonary blood flow typically present with cyanosis without associated symptoms of CHF. If the restriction is severe, pulmonary blood flow may be dependent upon a left-to-right shunt through the ductus arteriosus. These patients typically have some degree of right ventricular hypertension. If the ductus closes profound cyanosis results. Lesions presenting primarily with cyanosis in the newborn period are discussed later.

Transposition of the Great Arteries

TGA accounts for 5% of all cases of cyanotic CHD and is the most common cyanotic cardiac defect in the newborn. There is a strong male predominance (60%–70%) but no other clear association between TGA and maternal conditions, teratogen exposure, or

• **Fig. 55.5** Series and Parallel Circulations. The series circulation in the normal newborn is compared with the parallel circulation in transposition of the great arteries (TGA). In TGA, survival after birth is dependent on mixing at either the atrial, ventricular, or great vessel level. Ao, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (From Wernovsky G: *Transposition of the great arteries*. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:1027–1084.)

genetic abnormalities. TGA is typically an isolated defect, with less than 10% of cases associated with extracardiac malformations.

In the most common form of TGA (D-TGA, complete transposition, or simple transposition), the aorta arises from the right ventricle anteriorly and slightly rightward of the pulmonary artery, which arises from the left ventricle. Desaturated blood returns to the right ventricle and is recirculated to the body via the aorta, while oxygenated blood returns to the left ventricle and is recirculated to the lungs. The end result is separate, parallel circulations (Fig. 55.5). Survival is dependent upon communication between the two circulations, typically in the form of bidirectional shunting at the PFO and PDA. With absent or small communications between the circulations, severe systemic acidosis and hypoxia develop after birth resulting in death.

Cyanosis is apparent within the first few hours of life and is not responsive to oxygen. Cardiac examination is typically normal with the exception of a loud single S₂. Because of the arrangement of the great vessels, the louder closure of the anterior aortic valve obscures closure of the more posterior pulmonary valve. Chest X-ray may be normal or reveal a narrow mediastinum with slight predominance of the right ventricle resulting in an “egg on a string” appearance. Pulmonary vascular markings are normal to slightly increased. ECG is typically normal but may reveal right ventricular hypertrophy. Echocardiogram reveals the transposed great vessels and is used to determine the size of the PFO and PDA and define any associated cardiac defects.

Initial management of infants with TGA is aimed at maintaining communication between the systemic and pulmonary circulations. Prostaglandin E₁ (PGE₁) is started to maintain patency of the ductus arteriosus (dose of 0.03–0.1 mcg/kg per min). In patients with a restrictive PFO, or with persistent hypoxia and acidosis despite a PDA, a balloon atrial septostomy is performed within the first 24 to 48 hours of life to encourage mixing at the atrial level. In the setting of adequate mixing, pulmonary overcirculation may develop as PVR drops. Surgical treatment is the arterial switch procedure (Fig. 55.6), typically performed within the first week after birth (Castaneda et al., 1989; Prifti et al., 2002).

While TGA is usually an isolated lesion, 40%–45% of patients have an associated VSD, 10% have a VSD with left ventricular outflow tract obstruction, and 5% have left ventricular outflow tract obstruction alone. In addition, there is a wide variety in coronary artery anatomy in patients with TGA. The clinical presentation of patients with TGA and VSD depends upon the size of the VSD. Those with a restrictive VSD present like patients with TGA and intact ventricular septum. Those with a large VSD may not demonstrate any symptoms initially. As PVR drops, symptoms of pulmonary overcirculation develop. Patients with restricted pulmonary blood flow (TGA with VSD and pulmonic stenosis) appear clinically similar to patients with TOF. The timing and type of surgical repair in patients with complex TGA are variable and beyond the scope of this chapter.

Double Outlet Right Ventricle

DORV is a relatively rare, diverse group of lesions characterized by the origination of both great vessels from the right ventricle and by the persistence of the subaortic and subpulmonary conus. There are multiple anatomic variations of this lesion that are commonly classified by the relationship of the great vessels to one another and/or by the location of the VSD to the great vessels (Fig. 55.7) (Anderson et al., 1983; Stellin et al., 1991; Mahle et al., 2008). With this in mind, there are four types of DORV, each with a slightly different neonatal presentation and surgical management.

DORV of the tetralogy type typically has normally related great vessels with a subaortic VSD. Because the subaortic conus is pulled anteriorly, the subpulmonary conus is typically smaller, resulting in variable obstruction to pulmonary blood flow. The clinical presentation and surgical management are similar to those of TOF.

DORV of the transposition type typically has malposed great vessels with the aorta located either anterior to or rightward of the pulmonary artery. The VSD is subpulmonary and directs flow into the pulmonary artery, resulting in transposition-like physiology. This lesion is frequently associated with variable obstruction to aortic blood flow and coarctation of the aorta. Surgical repair consists of baffling the VSD to the pulmonary valve and performing an arterial switch. In the setting of coronary artery anomalies that prevent an arterial switch, the left ventricle is baffled to both the aortic and pulmonary valves, and a right-ventricle-to-pulmonary-artery conduit is placed. Arch obstruction is corrected if needed.

In DORV with a “doubly committed” VSD, the VSD is below both great vessels. The physiology and clinical presentation are variable, depending upon the size and orientation of the VSD and the degree of outflow tract obstruction. Surgical repair is directed at closing the interventricular communication without obstructing either ventricular outflow.

The least common variety of DORV is that in which the VSD is remote from both great vessels. Because of the distance between the VSD and the great vessels, a two-ventricle repair is difficult and often impossible. Pulmonary banding is frequently performed in the newborn period to limit pulmonary blood flow, delaying attempts at a biventricular repair or single ventricle palliation until several months of age. Recently, there has been increasing interest in biventricular repair for this lesion through creative intracardiac baffles (Lacour-Gayet, 2002).

Truncus Arteriosus

In truncus arteriosus, a single arterial trunk gives rise to the pulmonary, systemic, and coronary circulation. The arterial trunk

• **Fig. 55.6** Arterial Switch Operation for Dextro-Transposition of the Great Arteries. (A) The *dashed lines* depict the planned location of transection of the great vessels. (B) The coronary arteries are removed with surrounding aortic wall as "buttons." (C) The coronary buttons are translocated to the posterior neoaortic root. (D) The Lecompte maneuver brings both pulmonary arteries anterior to the neo-aorta. The aortic suture line is completed, incorporating the coronary buttons. The coronary donor sites are filled in with patches of autologous pericardium, and the pulmonary anastomosis is completed. (From Wernovsky G, Jonas RA. Transposition of the great arteries. In: Chang AC, Hanley FL, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore, MD: Williams & Wilkins; 1998:289–301.)

• **Fig. 55.7** Echocardiographic Views of Double Outlet Right Ventricle. (A) The aorta is committed to the right ventricle, and the ventricular septal defect is below the aortic valve. (B) The great vessels are transposed in this patient with the pulmonary artery overriding the ventricular septal defect.

• **Fig. 55.8** Types of Truncus Arteriosus. The classification of truncus arteriosus is determined by the origin of the pulmonary arteries (see text for details).

typically overrides a VSD. Truncus is classified by the origin of the pulmonary arteries (Fig. 55.8). In type I, a small pulmonary artery arises from the arterial trunk and bifurcates in the right and left branch pulmonary arteries. The right and left pulmonary arteries can also arise from separate ostia that are either close to one another (type II) or some distance apart (type III) (Collett and Edwards, 1949). Type IV is similar to TOF with pulmonary atresia. The truncal valve has between one and six cusps. It is occasionally insufficient but rarely stenotic. Truncus usually occurs as an isolated cardiovascular defect although has been associated with microdeletion of chromosome 22q11 (McElhinney et al., 2003).

As the PVR drops over the first several weeks after birth, increased shunting from the arterial trunk to the pulmonary arteries occurs, and pulmonary overcirculation develops. If left untreated, symptoms of heart failure develop. Long-term pulmonary vascular obstructive disease occurs.

The clinical presentation of truncus changes with the PVR. Initially, infants are minimally cyanotic and do not appear to be in distress. As pulmonary overcirculation occurs, symptoms of heart failure develop. Cardiac examination reveals a hyperdynamic precordium and a loud single S₂. As PVR drops, the pulses become bounding, and the pulse pressure widens because of run-off into the pulmonary arteries. A low-pitched diastolic inflow rumble may be heard at the apex. In addition, a systolic ejection murmur may be present and a medium- to high-pitched diastolic murmur may be heard from truncal valve insufficiency. Chest X-ray typically reveals cardiomegaly with pulmonary vascular marking that increases over the first few weeks of life. ECG demonstrates right, left, or biventricular hypertrophy. Echocardiogram is used to demonstrate the anatomy and evaluate for associated cardiac defects such as right aortic arch, coronary artery anomalies, interrupted aortic arch, and secundum ASDs.

Initially, heart failure symptoms are managed with medications. Surgical repair is typically performed within the first 2 months of life because of the difficulty in controlling heart failure. The usual repair involves closure of the VSD so that the arterial trunk arises from the left ventricle. A right-ventricle-to-pulmonary-artery conduit is then placed (Fig. 55.9). The right-ventricle-to-pulmonary-artery conduit needs to be replaced several times over the course of the patient's lifetime.

Total Anomalous Pulmonary Venous Return

In TAPVR, the pulmonary veins return to a systemic vein or directly to the right atrium, rather than to the left atrium. Both systemic and pulmonary venous return pass through the right atrium, right ventricle, and pulmonary artery, creating pulmonary overcirculation and right heart volume overload. An ASD is present in all cases. The right-atrium-to-left-atrium shunt supplies the

• **Fig. 55.9** Anatomy and Repair of Truncus Arteriosus. After the branch pulmonary arteries are removed from the common trunk (and the resulting aortic defect is closed), a ventriculotomy is performed. The ventricular septal defect is closed through this incision, and a conduit is placed from the right ventricle to the pulmonary arteries. (From Behrendt DM, Dick M. Truncus repair with a valveless conduit in neonates. *J Thorac Cardiovasc Surg.* 1995;110:1148–1150.)

systemic cardiac output. If the ASD is restrictive, then systemic output will be limited.

Several common patterns of anomalous pulmonary venous return are seen (Fig. 55.10) (Edwards and Helmholtz, 1956). Most commonly, the anomalous veins drain in a supracardiac fashion, entering the left innominate vein or SVC via a vertical vein and draining into the right atrium via the SVC. Cardiac drainage occurs when the anomalous veins drain into the right atrium via the coronary sinus. Alternatively, a descending vein may pass through the diaphragmatic hiatus and enter the hepatic or portal venous system resulting in infracardiac drainage. Rarely, a mixed pattern of drainage may exist, or the anomalous veins may drain directly into the right atrium. Drainage directly into the right atrium occurs almost exclusively in patients with heterotaxy.

The clinical presentation of TAPVR varies, depending upon the degree of obstruction to pulmonary venous flow. Patients with unobstructed pulmonary venous flow will have minimal symptoms in the newborn period, and cyanosis is usually not apparent. Symptoms of right heart failure develop over time because of the progressive right heart volume overload. Physical examination may reveal a right ventricular heave, fixed split S₂, and a soft systolic ejection murmur in the pulmonic area. Chest X-ray may demonstrate cardiomegaly due to an enlarged right atrium, right ventricle, and main pulmonary artery. Pulmonary vascular markings increase over time. ECG reveals peaked P waves and right ventricular hypertrophy. Patients with moderate restriction to pulmonary blood flow are typically cyanotic in the newborn period. There is usually adequate mixing of venous return to allow for oxygen delivery to tissues. These patients may, however, benefit from supplemental oxygen, mechanical ventilation, and sedation to decrease oxygen consumption. The presentation of patients with obstructed

pulmonary blood flow will be discussed later in this chapter under obstructive lesions.

Treatment of TAPVR is surgical. In most cases, a pulmonary venous confluence is seen near the left atrium. Cardiac catheterization is used to define pulmonary venous anatomy if the pulmonary veins are not well seen by echocardiography. During surgery, the pulmonary venous confluence is anastomosed to the left atrium, the ASD is closed, and the connections to systemic veins are ligated. In the absence of pulmonary venous obstruction and in the setting

of uncomplicated anatomy, surgical mortality is low and long-term results are good. Late pulmonary venous obstruction occurs in approximately 20% of cases, with relatively poor surgical and interventional cardiac catheterization results.

Tetralogy of Fallot

TOF consists of a VSD, overriding aorta, RVOT obstruction, and right ventricular hypertrophy (Fig. 55.11). The severity and location of the RVOT obstruction are variable. Infundibular hypertrophy, a small, frequently bicuspid pulmonary valve, and small main pulmonary artery can jointly or independently create obstruction at the subvalve, valve, or supravalve level, respectively. Complete obstruction of the RVOT (pulmonary atresia) with a VSD is an extreme form of TOF. TOF is associated with a right aortic arch in 20% of the cases and aberrant coronary arteries in 5%–10% of cases, both of which can affect surgical planning. The etiology of TOF is heterogeneous. Maternal diabetes, phenylketonuria, and retinoic acid exposure have been associated with TOF. In addition, genetic syndromes including 22q11 deletion, Alagille syndrome, and VACTERL/VATER association have been associated with TOF.

The pathophysiology and clinical presentation of TOF are directly tied to the severity of the RVOT obstruction. With mild RVOT obstruction, the predominant shunt through the VSD is left to right. Cyanosis is minimal, and symptoms of heart failure are the typical presenting symptoms. The main and branch pulmonary arteries are usually of normal size. With moderate RVOT obstruction, the shunt through the VSD is right to left, but the prograde flow through the RVOT is adequate, resulting in mild cyanosis. The main and branch pulmonary arteries may have areas of focal stenosis or be diffusely small. With severe RVOT obstruction, there is minimal or no prograde flow across the RVOT. Pulmonary blood flow is thus dependent upon left-to-right shunt through the PDA. Patients are severely cyanotic. PDA closure leads to cardiovascular collapse. The main and branch pulmonary arteries may be confluent and small. With pulmonary atresia (pulmonary atresia VSD or tetralogy pulmonary atresia), the pulmonary vascular bed is variable. The pulmonary arteries can be confluent, normal-sized, and fed entirely by the ductus arteriosus; confluent and small with a small ductus; or virtually absent with pulmonary blood flow supplied by multiple AP collateral vessels.

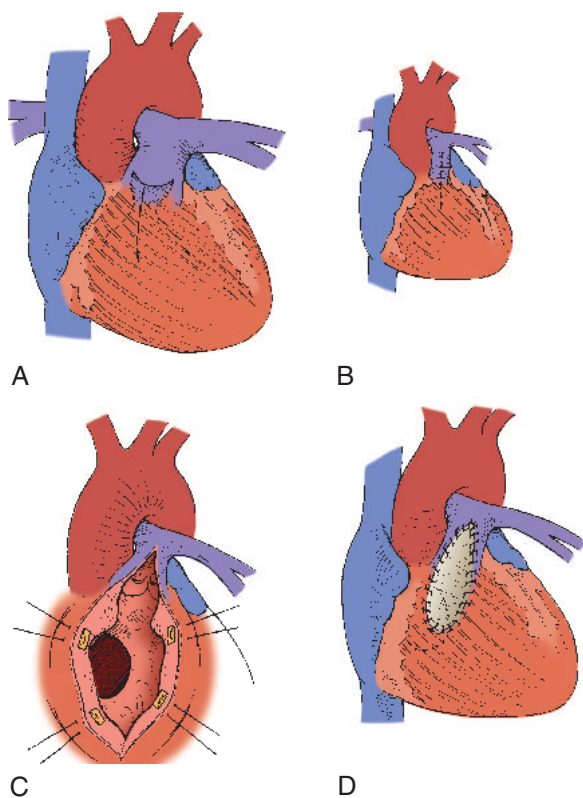

Initial management depends upon the amount of pulmonary blood flow. Patients without significant symptoms or hypoxemia undergo a complete repair in the first 6 months after birth. Complete repair consists of VSD closure and relief of RVOT obstruction through a combination of infundibular muscle resection, pulmonary valvotomy, or RVOT patch that can extend out to the branch pulmonary arteries as needed (Fig. 55.12). In patients with significant cyanosis or ductal-dependent circulation, management options include palliation with a systemic-to-pulmonary artery shunt in the newborn period (modified Blalock–Taussig [BT] shunt) and complete repair at a later date or a complete anatomic correction in the newborn period. The recent trend has been toward earlier complete correction in symptomatic infants (Reddy et al., 1995; Ooi et al., 2006; Tamesberger et al., 2008).

Tetralogy of Fallot Absent Pulmonary Valve

TOF with absent pulmonary valve (APV), or APV syndrome, is a spectrum of disorders with a rudimentary pulmonary valve. The resultant pulmonary valve stenosis and insufficiency cause dilation

• **Fig. 55.11** Echocardiographic View of Tetralogy of Fallot. (A) Some of the anatomic features of tetralogy of Fallot are readily demonstrated on the long-axis echocardiographic view including the hypertrophy of the right ventricle, the ventricular septal defect (VSD), and the aorta overriding the VSD. B. The short-axis view on echocardiogram shows the infundibular or right ventricular outflow tract stenosis.

• **Fig. 55.12** Repair of Tetralogy of Fallot. (A) Dashed line depicts a non-transannular incision, used when the pulmonary valve and annulus are of adequate size. (B) A transannular incision (dashed line) is used when there is annular hypoplasia. (C) An example of transventricular exposure of the ventricular septal defect. Alternatively, the ventricular septal defect may be closed via a right atriotomy through the tricuspid valve. (D) External view of patch closure of the transannular incision. (From Spray TL, Wernovsky G. Right ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore, MD: Williams & Wilkins; 1998:257–270.)

of the right ventricle and main and branch pulmonary arteries that is apparent in utero (Fig. 55.13). The vast majority of cases also have a malalignment VSD. Presumably secondary to airway compression by the dilated pulmonary vasculature, this syndrome is commonly associated with airway anomalies. There is a high prevalence of 22q11 deletion among patients with APV.

Physical examination reveals a characteristic “to and fro” murmur of pulmonary stenosis and insufficiency. A prominent right ventricular heave and hepatomegaly are present secondary to the right ventricular volume overload. There is a wide range of symptoms, depending upon the degree of right ventricular volume overload and degree of airway disease. At one end of the spectrum is an asymptomatic neonate with mild cyanosis and the gradual development of heart failure symptoms during the normal postnatal decline in PVR. At the other end of the spectrum is a critically ill infant with severe cyanosis and respiratory failure caused by the combination of right-to-left shunt through the VSD and underlying airway disease. Mechanical ventilation is necessary and occasionally unsuccessful secondary to airway compression by the dilated pulmonary vasculature. Urgent surgery is required in these infants.

Surgery consists of VSD closure, pulmonary artery plication, relief of RVOT obstruction, and insertion of a valve or homograft in the RVOT position. There is significant variation in surgical technique between centers (Alsoufi et al., 2007b; Tissot et al., 2007). The surgical mortality and short-term and long-term outcomes are related primarily to the severity of pulmonary artery dilation and airway compression. More severely affected infants have a higher surgical mortality and need for prolonged postoperative ventilation. Those with less significant pulmonary artery dilation have low postoperative mortality and long-term outcomes similar to those with TOF.

Pulmonary Atresia With Intact Ventricular Septum

In pulmonary atresia with intact ventricular septum, the pulmonary valve leaflets are fused or fail to form. Without egress from the

• **Fig. 55.13** Tetralogy of Fallot With Absent Pulmonary Valve. Severe dilatation of the main and branch pulmonary arteries is seen and is frequently associated with bronchial compression and large and small airway disease. The intracardiac anatomy is usually similar to that in standard tetralogy of Fallot. (From Spray TL, Wernovsky G. Right ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore, MD: Williams & Wilkins; 1998:257–270.)

right ventricle, systemic venous return passes through the PFO and mixes with pulmonary venous return. Pulmonary blood flow is dependent upon the PDA, with the left ventricle providing cardiac output to both the systemic and pulmonary circulations. Tricuspid valve and right ventricular size vary, ranging from nearly normal-sized structures to nearly atretic tricuspid valve and diminutive right ventricle chamber. The latter patients may have sinusoidal channels in the right ventricle myocardium that communicate with the coronary circulation. The high right ventricular pressure results in retrograde perfusion of the coronary arteries, resulting in right ventricle-dependent coronary circulation (Fig. 55.14).

Pulmonary atresia with intact ventricular septum presents with cyanosis. Cardiac examination reveals a single loud second heart sound. A murmur is typically not present, other than from the PDA. ECG typically reveals a relative lack of right-sided forces with a QRS axis between 0 and 90 degrees. The P wave is peaked from right atrial enlargement. Pulmonary vascular markings on chest X-ray are typically decreased. Echocardiography confirms the diagnosis and can be used to look for coronary sinusoids. Cardiac catheterization is performed in patients where coronary sinusoids are known or suspected to completely define the extent and connections of the sinusoids.

Initially, PGE₁ is used to maintain ductal patency until a more permanent source of pulmonary blood flow is provided. In patients with right ventricle-dependent coronary circulation, the outcome of surgical repair is often poor. A systemic-to-pulmonary shunt followed by staged single ventricle palliation may be tried, but proceeding directly to heart transplantation may be appropriate. In patients without right ventricular coronary-dependent circulation, an egress from the right ventricle to pulmonary arteries is created by surgical valvotomy or RVOT augmentation or valve perforation,

• **Fig. 55.14** Lateral Angiogram From a Newborn With Pulmonary Atresia and Intact Ventricular Septum. Following injection of contrast through the hypertrophied and diminutive right ventricle, there is retrograde filling of tortuous coronary arteries through sinusoidal connections to the right ventricle (arrows). RV, Right ventricle.

• **Fig. 55.15** Newborn Surgical Palliation for Pulmonary Atresia With Intact Ventricular Septum and Normal Coronary Arteries. A right ventricular outflow tract patch is placed, the ductus is ligated and divided, and a modified Blalock-Taussig shunt is placed. (From Wernovsky G, Hanley FL. Pulmonary atresia with intact ventricular septum. In: Chang AC, Hanley FL, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore, MD: Williams & Wilkins; 1998:265–270.)

and valvuloplasty is performed in the catheterization lab (Fig. 55.15) (Justo et al., 1997). At times, additional pulmonary blood flow is provided by a modified BT or other systemic-to-pulmonary shunt. The postoperative course can be complicated by low cardiac output or a circular shunt.

• **Fig. 55.16** Anatomic Variants in Tricuspid Atresia. (A) Normally related great vessels with a large ventricular septal defect (VSD) and normal-sized pulmonary arteries (PAs). (B) Normally related great vessels with a small VSD and PAs. (C) Transposed great arteries (left ventricle aligned with the PA, right ventricle with the aorta) with a relatively small VSD and aorta. Many patients with this variant have coarctation as well (see text). (D) Transposed great vessels with a VSD, subpulmonary obstruction, and small PAs. (From Fyler DC. Tricuspid atresia. In: Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia, PA: Hanley & Belfus; 1992:659–667.)

Tricuspid Atresia

In tricuspid atresia, there is no outlet from the right atrium to the right ventricle. Systemic venous return passes from the right atrium, through a PFO or ASD, to the left ventricle. More than 90% of patients with tricuspid atresia have an associated VSD, allowing blood to pass from the left ventricle to the pulmonary arteries (Fig. 55.16). The size of the VSD determines the amount of pulmonary blood flow. Patients with a small or absent VSD have a very hypoplastic right ventricle and pulmonary artery. The majority of pulmonary blood flow passes through the PDA. If a large VSD is present, pulmonary blood flow is prograde through the pulmonary valve, and the ductus is not necessary. A variant of tricuspid atresia is associated with TGA. Pulmonary blood flow is derived from the left ventricle, and systemic blood flow must pass through the VSD. There may be an associated coarctation or hypoplastic aortic arch in these patients.

Clinically, cyanosis is present at birth, the extent of which is dependent upon the degree of restriction to pulmonary blood flow. A holosystolic murmur consistent with a VSD and a prominent left ventricular impulse are present on exam. ECG is nearly diagnostic and reveals left axis deviation and left ventricular hypertrophy. Chest X-ray reveals variable pulmonary vascular markings, depending on the size of the VSD and relationship of the great vessels. Echocardiogram demonstrates a fibromuscular plate in place of the tricuspid valve and a variably small right ventricle and pulmonary valve. The relationship of the great vessels can also be determined by echocardiogram. The degree of obstruction at the VSD or across the RVOT can be evaluated.

PGE₁ is used initially to maintain a PDA. If there is restriction to flow at the atrial level, a balloon septostomy is performed. Further management depends on the amount of pulmonary blood flow and the relationship of the great vessels. Patients with ductal-dependent pulmonary blood flow have a systemic-to-pulmonary artery shunt placed (modified BT shunt). Those with adequate pulmonary blood flow undergo a SVC-to-pulmonary-artery anastomosis (bidirectional Glenn) at approximately 6 months of age, with completion of the Fontan procedure around 3 years of

age. Patients with transposition, or more complex anatomy, undergo more extensive palliative procedures initially but continue down the pathway to Fontan palliation.

Ebstein Anomaly of the Tricuspid Valve

Ebstein anomaly is a rare form of CHD with variable presentation. Dysplasia of the tricuspid valve, with downward displacement of the septal and posterior leaflets, is the defining feature (Fig. 55.17). The anterior leaflet, although normally positioned in the valve annulus, frequently has abnormal chordal attachments and is large and redundant. The tricuspid valve abnormality can be accompanied by tricuspid regurgitation, right atrial dilation, abnormal right ventricular myocardium, and an increased risk of Wolf–Parkinson–White syndrome. In addition, functional and true pulmonary atresia can occur with severe Ebstein malformation. With displacement of the tricuspid valve, a significant portion of the right ventricle becomes atrialized, making it an ineffective pumping chamber. In this setting it can be difficult to differentiate functional pulmonary atresia from true pulmonary atresia. Severe Ebstein anomaly of the tricuspid valve is associated with heart failure in utero (Tongsong et al., 2005).

The clinical presentation is variable and depends upon the degree of displacement of the tricuspid valve and severity of RVOT obstruction. In many patients, symptoms are mild and do not present until later in life. In more severe disease, cyanosis results when a right-to-left shunt occurs at the atrial level, secondary to the tricuspid regurgitation and elevated right atrial pressures. Cardiac examination reveals a holosystolic murmur at the lower left sternal border with associated gallop and clicks. Neonates with severe Ebstein present with marked cyanosis, cardiomegaly, and ductal-dependent pulmonary blood flow. Chest X-ray is characteristic in severe cases with severe cardiomegaly evident at birth (Fig. 55.18). Death can occur because of the significant heart failure and hypoxemia. Clinical improvement may occur as the PVR drops, improving the right ventricle's ability to contribute to pulmonary blood flow.

Initially, management of the severely cyanotic infant is aimed at promoting pulmonary blood flow. PGE₁ is used to maintain

• **Fig. 55.17** Inferior Displacement of Tricuspid Valve Leaflet Into the Right Ventricular Cavity. The *white arrowheads* indicate the normally positioned tricuspid valve annulus. The asterisks (*) indicate varying degrees of inferior or apical displacement of the septal leaflet of the tricuspid valve. The area between the true annulus and the displaced valve leaflet is considered "atrialized." (From Epstein ML. Congenital stenosis and insufficiency of the tricuspid valve. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, eds. *Moss and Adams' Heart Disease in Infants, Children and Adolescents: Including the Fetus and Young Adult*. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:810–819.)

• **Fig. 55.18** Chest Radiograph in a 1-Day-Old Newborn With Ebstein Anomaly of the Tricuspid Valve. Note the massive cardiomegaly and relative pulmonary oligemia and hypoplasia.

ductal patency. Supplemental oxygen, inhaled nitric oxide, and mild respiratory alkalosis can have marginal success in improving pulmonary blood flow by lowering PVR. After several days, attempts are made at weaning the PGE₁. If unsuccessful, surgical options are considered. Options include tricuspid valve repair or replacement, 1½ ventricle repair, or other palliative procedures such as right ventricular exclusion with a fenestrated patch and placement of a modified BT shunt (Reemtsen et al., 2007). While surgical outcomes have improved, the need for neonatal repair for symptomatic disease remains a risk factor for death (McElhinney et al., 2005; Sarris et al., 2006).

Lesions That Present Primarily With Heart Failure

Hypoplastic Left Heart Syndrome

HLHS is an anatomically heterogeneous lesion characterized by varying degrees of underdevelopment of the left ventricle, hypoplasia or atresia of the aortic and mitral valves, and hypoplasia of the aortic arch. While accounting for only 1.4%–3.8% of all congenital heart defects, HLHS accounts for 23% of cardiac deaths in the first week of life and 15% of cardiac deaths in the first month after birth (Samaneck, 2000). HLHS is likely multifactorial in cause. There is a slight male predominance. While there is no clear genetic cause, familial clustering of various left heart obstructive lesions has been noted.

It is theorized that the growth of developing vascular structures is dependent upon flow. HLHS likely results from in utero obstruction of left ventricular inflow or outflow. The fetal left ventricle is predominantly filled with blood that passes through the foramen ovale. Restriction to flow or reversal of flow through the foramen ovale could then result in decreased flow to the left heart and its underdevelopment. Similarly, several studies have documented the progression of severe aortic stenosis to HLHS in utero (Danford and Cronican, 1992; Hornberger et al., 1995). The progressive left ventricular hypertrophy, dilation, and fibrosis associated with severe aortic stenosis can lead to decreased ventricular compliance, elevated left atrial pressures, and reversal of flow through the foramen ovale in utero. Prenatal cardiac intervention is still in its infancy, and much continues to be learned about fetal intervention, but successes with in utero balloon dilation of the aortic valve suggest that the progression to HLHS can be altered (Makikallio et al., 2006; McElhinney et al., 2010).

Because of the underdevelopment of the left heart structures, pulmonary venous return must exit the left atrium through the foramen ovale. Pulmonary venous blood then mixes with systemic venous return in the right atrium and enters the right ventricle. Right ventricular output then passes either into the pulmonary circulation or through the ductus arteriosus into the systemic circulation; that is, the pulmonary and systemic circulations are in parallel. The ratio of systemic to pulmonary blood flow is determined by the relative resistance of the vascular beds. As the normal postnatal drop in PVR occurs, pulmonary flow increases at the expense of systemic flow. Thus the management of HLHS is dependent upon an adequate egress from the left atrium and a balancing of the resistances of the pulmonary and systemic vascular beds.

Most cases of HLHS are now diagnosed prenatally when an abnormal four chamber view of the heart is noted on a screening obstetric ultrasound. Ideally, delivery should occur at a tertiary care center. In the absence of prenatal diagnosis, postnatal

presentation is somewhat variable and dependent upon ductal patency and the degree of restriction to flow at the atrial septum. The infant with an unrestrictive atrial septum and PDA is largely asymptomatic at birth and may be missed in the newborn period. Cyanosis is minimal and pulmonary overcirculation is mild while PVR is high. Cardiac exam is relatively unremarkable. The second heart sound is single and loud. A third heart sound becomes apparent as heart failure develops. As PVR drops and ductal closure occurs, feeding difficulties and respiratory distress become apparent with rapid progression to cardiovascular collapse. Physical examination following ductal restriction is significant for lethargy, pallor, and diminished or absent pulses. Chest X-ray typically reveals a relatively normal-sized heart and pulmonary edema. ECG is nonspecific but may reveal relative lack of left-sided forces.

The patient with a restrictive atrial septum presents with tachypnea and profound cyanosis shortly after birth. The elevated left atrial and pulmonary venous pressures result in pulmonary venous congestion that is apparent on chest X-ray.

The preoperative management of patients with HLHS is directed at balancing the ratio of pulmonary-to-systemic blood flow ($Q_p : Q_s$) to allow for sufficient oxygenation of blood while maintaining adequate systemic cardiac output. Prostaglandins should be started immediately postnatally to ensure ductal patency. Echocardiography is utilized to confirm cardiac anatomy and determine the degree of restriction to flow through the foramen ovale. If the atrial level shunt is restrictive with profound cyanosis and metabolic acidosis, a balloon atrial septostomy, surgical septectomy, or emergent stage I palliation should be performed (see later in the section). If the restriction was present in utero, pathologic fibrosis and arterialization of the pulmonary veins and medial hypertrophy of the pulmonary arterioles occur. Even following atrial septostomy, lung disease can persist and PVR can remain high. Oxygen may be needed to maintain saturations in an appropriate range. This subset of patients has a high mortality rate.

A small group of patients will have adequately balanced pulmonary and systemic blood flow at the time of presentation. A small degree of restriction to flow through the foramen ovale may be associated with slight cyanosis but has the beneficial effect of restricting pulmonary blood flow. In the absence of acidosis or end-organ dysfunction, this state is generally tolerated until stage I palliation is performed.

An unrestrictive ASD allows increased pulmonary blood flow as the PVR falls. Because of the parallel arrangement of the circulations, increasing pulmonary flow decreases systemic flow. In this setting, there is increasing oxygen saturation associated with inadequate oxygen delivery to the tissues. Worsening metabolic acidosis and end-organ dysfunction ensue. The ratio of pulmonary-to-systemic blood flow is balanced by manipulating the resistances of the pulmonary and systemic vascular beds. The success of these therapies is monitored by measurement of oxygen saturation, mixed venous saturation, lactate, and arterial blood gases.

PVR can be manipulated through mechanical ventilation and alteration in the amount of oxygen delivered. Mechanical ventilation with high positive end-expiratory pressure can limit pulmonary blood flow. PVR can also be increased by adding carbon dioxide or nitrogen to the ventilator circuit to reduce the fraction of inspired oxygen (FiO_2) to 0.17 (Riordan et al., 1996; Shime et al., 2000). Both CO_2 and nitrogen have been shown to decrease the $Q_p : Q_s$ and decrease oxygen saturation. Only hypercarbia has been shown to improve systemic oxygen delivery (Tabbutt et al., 2001). The goal of this therapy is to maintain normal lactate systemic oxygen saturation at 75%–85% and mixed venous oxygen saturation

approximately 25 percentage points lower than systemic saturations. Mechanical ventilation is typically required when manipulating inspired gas. Mechanical ventilation alone has been associated with increased infection risk, more labile preoperative hemodynamics, and increased mortality. Both elective mechanical ventilation and alteration of the inspired gas mixture may be less in favor in the current era (Johnson et al., 2008).

Vasoactive medications can be used to alter systemic vascular resistance and improve ventricular function. Use of these medications is determined by clinical presentation and echocardiographic findings. Milrinone can be used to provide some afterload reduction, if tolerated by blood pressure. The inotropic effects of milrinone are also an advantage if ventricular function is poor. In addition to decreasing pulmonary blood flow, afterload reduction has the added benefit of decreasing tricuspid valve regurgitation if it is present. Milrinone also dilates the pulmonary vascular bed, so care should be taken when it is used. While counterintuitive, when faced with an unoperated patient with high oxygen saturation and low peripheral blood pressure, the gentle addition of milrinone may improve blood pressure simply by increasing systemic blood flow (Johnson et al., 2008).

The immediate goal of surgical palliation is to provide stable unrestricted systemic and coronary blood flow and reliably restricted pulmonary blood flow. There are several strategies for stage I palliation. Traditionally, aortic arch reconstruction was performed using pulmonary artery tissue, and pulmonary blood flow was supplied using a modified BT shunt (Norwood procedure, Fig. 55.19). A recent modification of a right ventricle-to-pulmonary artery conduit has been used to supply pulmonary blood flow (Sano modification, Fig. 55.20). The Sano modification has the presumed benefit of providing pulsatile flow to the pulmonary arteries without AP diastolic run-off and coronary steal. The downside of this procedure is the need for a ventriculotomy. A hybrid procedure that combines stent placement in the ductus arteriosus by the cardiologist and pulmonary artery banding by the surgeon is an approach being taken by a number of institutions and provides a relatively noninvasive stage I palliation for HLHS (Caldarone et al., 2007). Each of these procedures has pros and cons and advocates and detractors (Malec et al., 2003; Ghanayem et al., 2006; Caldarone et al., 2007). Longer-term prospective studies are needed to determine the optimal approach to stage I palliation. In the low-risk patient, survival following the first stage nears 80%–90%.

The remaining palliative surgeries occur outside the newborn period. Stage II palliation unloads the right ventricle and begins to separate the pulmonary and systemic circulations. The superior cavopulmonary anastomosis (bidirectional Glenn) is usually performed between 4 and 6 months of age. During this procedure, the conduit providing pulmonary flow is removed, and the SVC is anastomosed to the pulmonary artery.

Stage III palliation completely separates the pulmonary and systemic circulations. An inferior cavopulmonary anastomosis (Fontan completion) is performed by one of several techniques.

Obstructed Total Anomalous Pulmonary Venous Return

Obstructed TAPVR represents one of the few remaining neonatal surgical emergencies in pediatric cardiology. While obstruction can occur with any type of TAPVR, it is most common in infra-diaphragmatic TAPVR. Physiologically, obstruction to pulmonary venous flow results in pulmonary venous hypertension that is transmitted to the pulmonary capillary bed, resulting in pulmonary

• **Fig. 55.19** Stage I Palliation for Hypoplastic Left Heart Syndrome: Classic Norwood Procedure. (A) The main pulmonary artery (a) is transected and the distal end oversewn. The ductus arteriosus is ligated, and an incision is made from the proximal ascending aorta around the aortic arch to the level of the ductus. (B) A pulmonary homograft is utilized to create a patch to reconstruct the neo-aorta. (C, D) This homograft patch is used to connect the proximal main pulmonary artery and pulmonary (neo-aortic) valve to the ascending aorta and transverse arch. (E) A modified Blalock-Taussig shunt is placed from the base of the innominate artery to the right pulmonary artery. (F) An alternate technique utilizing a circumferential tube graft from the proximal main pulmonary artery to the distal transverse aortic arch. *Not shown:* Atrial septectomy is performed to provide unobstructed egress from the pulmonary veins to the right ventricle. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL. *Cardiac Surgery of the Neonate and Infant*. Philadelphia, PA: WB Saunders; 1994.)

• **Fig. 55.20** Right Ventricle–Pulmonary Artery, or Sano, Modification of Stage I Reconstruction. The arch reconstruction is similar to that shown in Fig. 55.19. The Blalock–Taussig shunt is replaced with a Gore-Tex tube inserted from the right ventricle to the main pulmonary artery. (From Sano S, Ishino K, Kawada K, et al. Right ventricle–pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg.* 2003;126:504–510.)

edema. Pulmonary blood flow is severely limited. Newborns thus present with profound cyanosis and respiratory distress that are not responsive to medical management. Prostaglandins may help minimize the obstruction by maintaining patency of the ductus venosus, but patency of the ductus arteriosus does not improve the clinical picture as the limitation to pulmonary blood flow is not due to insufficient antegrade flow but rather obstructed outflow. Chest X-ray reveals a normal cardiac silhouette with pulmonary venous congestion that may be interpreted as interstitial pneumonia (Fig. 55.21). Echocardiography can be challenging in these patients. The pulmonary veins can be small due to limited flow, making them difficult to detect by two-dimensional imaging and color Doppler. Surgical treatment is the same as for unobstructed TAPVR. The postoperative course is frequently marked by PVR lability, right ventricular hypertension, and low cardiac output syndrome. The risk of mortality, need for prolonged ventilation, and incidence of late postpresence of postoperative obstruction all increase when obstruction is present preoperatively (Frommelt et al., 2010).

Cor Triatriatum

Embryologically, the pulmonary veins enter a common pulmonary vein that initially has no connection to the left atrium (Neill, 1956). During normal development, the common pulmonary vein becomes incorporated into the left atrium, resulting in the usual pattern of two right and two left pulmonary veins entering the left atrium. Abnormal incorporation of the common pulmonary vein can result in cor triatriatum, a condition in which the common pulmonary vein joins the left atrium through a single opening. If the opening is small and restrictive, the clinical presentation is similar to that of obstructed TAPVR. If the opening is nonrestrictive, no symptoms are present. Surgical resection of the membrane that separates the left atrium and common pulmonary vein is an effective

• **Fig. 55.21** Chest X-Ray in a 1-Day-Old With Obstructed Total Anomalous Pulmonary Venous Return.

treatment. Significant preoperative pulmonary venous obstruction increases surgical mortality.

Mitral Stenosis

Congenital mitral stenosis is a rare form of CHD with several subtypes. The stenosis can occur in the supravalue region, at the valve annulus, or within the mitral valve support apparatus. Typical congenital mitral stenosis is characterized by thickened leaflets, short or absent chordae tendinae, obliteration of interchordal spaces, and two separate papillary muscles. Supravalar mitral ring occurs when there is connective tissue outgrowth on the atrial surface of the mitral valve leaflets, leading to a decreased mitral valve orifice. The mitral valve orifice can also be stenotic secondary to a parachute mitral valve, when most or all chordae tendinae insert onto only one papillary muscle. Another form of obstruction occurs with a double orifice mitral valve, where a tongue of tissue connects the anterior and posterior mitral valve leaflets. A mitral arcade or hammock occurs when the leaflets are connected directly or by short chordae to the papillary muscles. Congenital mitral stenosis frequently occurs in conjunction with other left-sided obstructive lesions.

Symptoms from mitral stenosis usually occur in the first 2 years of life and may consist of shortness of breath, respiratory distress or wheezing, cyanosis, and pallor. Cardiac examination reveals a rumbling apical diastolic murmur, loud first heart sound, and loud split second heart sound. Opening snap of the mitral valve may be heard. Chest X-ray reveals left atrial enlargement and pulmonary venous congestion. ECG reveals right ventricular hypertrophy (RVH) with normal, bifid, or spiked P waves suggesting left atrial enlargement (LAE). Echocardiogram is used to define mitral valve anatomy and localize the area of obstruction. Doppler can be used to determine valve gradient and estimate right ventricular pressure.

Treatment options for congenital mitral valve stenosis include balloon mitral valvuloplasty, surgical mitral valvuloplasty, and mitral valve replacement. Despite recent improvements in outcomes, intervention and mitral valve replacement have relatively poor

short-term outcomes (Baird et al., 2015; Myers et al., 2015). Patients with additional left-sided obstructive lesions or associated defects frequently require single ventricle palliation.

Critical Aortic Stenosis

Patients with critical aortic stenosis have severe left ventricular outflow tract obstruction that limits systemic cardiac output (Fig. 55.22). The result is ductal-dependent systemic perfusion. While the obstruction can occur below the valve, at the valve, above the valve, or as a combination of these, this section focuses on outflow tract obstruction resulting from morphologic problems of the aortic valve. Severe aortic valve stenosis is defined as a Doppler-derived pressure gradient greater than 60 mmHg. Moderate stenosis is defined as gradient of 30–60 mmHg, while mild stenosis is a peak gradient less than 30 mmHg. In the setting of depressed left ventricular function, the Doppler echocardiogram-derived gradient may be significantly lower and underestimate the severity of the stenosis.

Aortic valve stenosis is detectable in utero. The long-standing pressure overload on the left ventricle causes left hypertrophy and left ventricle scarring (endocardial fibroelastosis). In some cases, as discussed above, the disease progresses to HLHS. Growing experience with fetal intervention suggests that, with proper patient selection, it is possible to alter the course of critical aortic stenosis in the fetus through early intervention (Freud et al., 2014; Friedman et al., 2015).

Clinically, critical aortic stenosis presents in the newborn period with signs of decreased systemic perfusion: pallor, decreased pulses, and prolonged capillary refill. A harsh ejection quality murmur is heard on examination in the aortic area. The volume and quality of the murmur correlate with the severity of stenosis in the setting of normal left ventricular function. If left ventricular function is depressed, the murmur may be soft despite severe stenosis. ECG reveals left ventricular hypertrophy with possible T-wave abnormalities. Heart size is typically normal on chest film, although the aortic knob may be prominent, and pulmonary congestion may be present. Echocardiogram is used to define the location and severity of the left ventricular outflow tract obstruction. Aortic stenosis is commonly found with other left-sided obstructive lesions, with possible underdevelopment of left heart structures. These

findings may alter the treatment plan and lead to single ventricle palliation. Published models have attempted to identify echocardiographic findings that predict the suitability of a two-ventricle repair in neonates with critical aortic stenosis (Rhodes et al., 1991; Lofland et al., 2001; Colan et al., 2006).

Initial management of infants with critical aortic stenosis is directed at the treatment of cardiogenic shock. Endotracheal intubation, mechanical ventilation, secure vascular access, inotropic support, sedation, and paralysis are all frequently necessary. PGE₁ maintains ductal patency and provides systemic output. A small PFO must be present for pulmonary venous return to cross the atrial septum and enter the systemic vascular via the right ventricle and ductus arteriosus. A balloon septostomy may be necessary to decompress the left atrium.

Further management depends on left ventricular size and the presence of other left heart obstructive lesions. Patients with multiple levels of left heart obstruction, a small mitral valve, hypoplastic aortic arch, or small left ventricle may be best suited for single ventricle palliation. Options for two-ventricle palliation include balloon valvuloplasty in the cardiac catheterization lab, surgical valvotomy, or neonatal Ross procedure (Fig. 55.23) (Alsoufi et al., 2007b). Outcomes of all procedures depend, in part, on relief of obstruction, presence of aortic valve regurgitation, associated cardiac lesions, and severity of end-organ dysfunction at the time of initial presentation. The mortality of each of the interventions is relatively high. Regardless of the treatment chosen, critical aortic stenosis is a lifelong illness. Patients require close follow-up and multiple procedures throughout their lifetime.

Coarctation of the Aorta

Coarctation may occur anywhere from the transverse aortic arch to the bifurcation of the iliac arteries. Most commonly, there is a discrete narrowing distal to the left subclavian artery, across from the aortic insertion of the ductus arteriosus in a *juxtaductal* position. Conversely, there can be long segment narrowing of the transverse aortic arch, otherwise referred to as a hypoplastic aortic arch. A bicuspid aortic valve occurs in 70% of cases. Other left-sided obstructive lesions tend to occur with coarctation of the aorta. There is a 2:1 male-to-female preponderance and an association with Turner syndrome.

In neonates with a discrete juxtaductal narrowing, the PDA widens the narrowed area and provides relief from the obstruction. The net shunt through the PDA is left to right. These patients have equal oxygen saturations in the upper and lower extremities. In patients with a severe coarctation or a diffusely hypoplastic arch, descending aortic flow originates from a right-to-left shunt through the ductus arteriosus. Differential upper and lower extremity oxygen saturations occur in these patients, with the upper extremities having greater saturation than the lower extremities.

The clinical presentation of coarctation of the aorta depends upon the severity of the narrowing. Mild coarctation often does not present in infancy. Detection typically occurs when upper extremity hypertension and diminished or absent femoral pulses are noted on examination. Infants with more severe coarctation or aortic arch hypoplasia present with diminished lower extremity perfusion following ductal closure. Physical examination reveals an infant with poor perfusion and absent femoral pulses. Cardiac examination may reveal a systolic ejection click if a bicuspid aortic valve is present. A systolic ejection quality murmur is heard that radiates to the back and left infraclavicular area. Chest film demonstrates a large heart with increased pulmonary vascular markings. ECG reveals

• **Fig. 55.22** Congenital Aortic Stenosis. Frontal view through opened aorta demonstrates stenotic and dysmorphic aortic valve with commissural fusion. (From Litwin SB. *Color Atlas of Congenital Heart Surgery*. St. Louis, MO: Mosby; 1996.)

• **Fig. 55.23** Ross Procedure: “Autograft” Aortic Valve Replacement. (A) Dashed lines depict surgical incisions around coronary arteries, aorta, and pulmonary artery. (B) Following removal of the coronary arteries and adjacent “buttons” and the diseased aortic valve, the patient’s native pulmonary valve (“autograft”) is positioned in the aortic root. (C) Completed repair with reimplanted coronary arteries and a cadaveric homograft valve inserted in the pulmonary position. (From Chang AC, Burke RP. Left ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore, MD: Williams & Wilkins; 1998:233–256.)

right ventricular hypertrophy. Echocardiogram is used to define the location and extent of aortic narrowing. Additional left-sided obstructive lesions are ruled out. Right ventricular hypertrophy and right ventricle hypertension are also frequently noted.

Treatment of the infant presenting with coarctation of the aorta is similar to that of infants with aortic stenosis. Intubation and mechanical ventilation are necessary. Vascular access is obtained for inotropes. PGE₁ is started to open the ductus arteriosus. Metabolic derangements are corrected. Ideally, the infant is stabilized before surgery. Surgery is typically indicated at the time of diagnosis, even in relatively asymptomatic patients. In most cases a lateral thoracotomy is performed, the area of coarctation is excised, and an end-to-end anastomosis is performed. If long segment narrowing is present, patch material may be used to augment the arch, and a more extended end-to-end anastomosis is performed. Balloon

angioplasty of native coarctation is not typically performed in infancy because of the risk of aneurysm, recoarctation, and vascular injury at the site of access.

Surgical mortality is slightly greater than 5% (Mery et al., 2015). Recoarctation occurs in 10%–15% of children and is successfully managed with balloon angioplasty. If a VSD is present, this is typically closed at the time of surgery.

Interrupted Aortic Arch

Interrupted aortic arch is a relatively rare anomaly that is defined simply as complete separation of the ascending and descending aorta. Interrupted aortic arch can be classified by the location of the interruption relative to the head and neck vessels (Fig. 55.24): type A, distal to the left subclavian artery; type B, between the

• **Fig. 55.24** Anatomic Classification of Interrupted Aortic Arch—Types A, B, and C. Dashed lines indicate the potential areas of discontinuity (interruption) in the aortic arch. See text for details. a, Artery. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL. *Cardiac Surgery of the Neonate and Infant*. Philadelphia, PA: WB Saunders; 1994.)

left subclavian and left carotid; and type C between the left carotid and innominate artery. All types of interruption occur in conjunction posterior malalignment of the infundibular septum; this results in a VSD and varying degrees of left ventricular outflow tract obstruction. Aberrant arrangements of the head and neck vessels are common, with 50% of patients with type B interruption having an aberrant right subclavian artery that arises from the descending aorta. Interrupted aortic arch is associated with 22q11 deletion.

The clinical presentation of interrupted aortic arch is similar to that of other left-sided obstructive lesions. Descending aortic flow is entirely dependent upon right-to-left shunting through the PDA. Ductal closure causes cardiovascular collapse. Initial management is as described for coarctation of the aorta. PGE₁ should be started as soon as possible, as all other resuscitative efforts will have no benefit until postductal circulation is established.

Surgical repair is performed after metabolic acidosis resolves and end-organ function is improved. Continuity is established between the ascending and descending aorta via end-to-end anastomosis, homograft insertion/patch augmentation to connect the two segments, or jump grafts (Fig. 55.25). The VSD is typically closed. In patients with severe left ventricular hypoplasia, a two-ventricle repair may not be possible, and a staged repair or single ventricle palliation is performed (Tchervenkova et al., 2005). Surgical mortality is less than 10% but higher in patients with additional anomalies (Shinkawa et al., 2012). Repeat operation because of left ventricular outflow tract obstruction and balloon angioplasty for recurrent arch obstruction are both common.

Anomalous Origin of the Left Coronary Artery From the Pulmonary Artery

When the left coronary artery arises from the pulmonary artery, inadequate oxygen delivery to the left ventricle results. Coronary artery perfusion occurs primarily during diastole. As pulmonary artery pressures drop postnatally, perfusion pressure of the left

coronary artery falls resulting in ischemia and infarction of the left ventricle. If collateral vessels connect the right and left coronary circulations, flow in the left coronary artery reverses. A left-to-right shunt occurs resulting in coronary artery steal. Mitral valve regurgitation secondary to papillary muscle ischemia and left ventricular dilation develops.

Clinically, symptoms typically develop in the first month after birth. If adequate collateral vessels and myocardial oxygen delivery exist, the patient may present later in life with angina-like symptoms. In the infant, attacks of irritability, pallor, and diaphoresis with feeds are a common presentation. Cardiac examination reveals a displaced point of maximal impulse (PMI), gallop rhythm, and nonspecific murmur. If mitral regurgitation is present, a holosystolic, regurgitant quality murmur is heard. Chest X-ray reveals massive cardiomegaly. The ECG demonstrates a QR pattern and inverted T waves in leads I and aVL. Leads V₅ and V₆ may also have deep Q waves, inverted T waves, and ST segment depression. Echocardiography may suggest the diagnosis but is not always reliable as the left coronary occasionally appears to arise from the aorta. Color Doppler may demonstrate retrograde flow in the left coronary with flow into the pulmonary artery. Cardiac catheterization is diagnostic.

Symptoms of CHF are managed medically. Surgical reimplantation of the left coronary artery to the aorta restores normal coronary perfusion pressure. If the usual two-vessel coronary blood supply is reestablished, there is gradual normalization of left ventricular size and function, as viewed by echocardiography (Lange et al., 2007; Kuroczynski et al., 2008). If myocardial damage is severe or the left coronary artery cannot be reimplanted surgically, cardiac transplantation is performed.

Systemic Arterial Malformations

Vascular anomalies are placed in two major groups: hemangiomas and malformations. Hemangiomas are tumors that demonstrate endothelial hyperplasia and which undergo a period of proliferation and involution. Malformations result from abnormal vascular morphogenesis. They have normal endothelial cell turnover and grow accordingly with surrounding structures. Vascular malformations are further subcategorized by the type of vascular tissue involved (arterial, venous, and lymphatic). Because of their association with high output failure in the newborn period, two types of systemic vascular malformations will be discussed further: AVMs and arteriovenous fistulas (AVFs). An AVM results from multiple microfistulas between small arteries and veins. An AVF results from a connection between a large artery and vein.

Hemodynamically significant AVFs and AVMs present with high output heart failure and cyanosis in the newborn period. An effective large left-to-right shunt occurs through the direct arterial-venous connections. Heart rate, stroke volume, plasma volume, and cardiac output are increased. The fistulous connection lowers systemic vascular resistance, promoting a right-to-left shunt through the ductus arteriosus, particularly if the normal postnatal drop in PVR has not occurred. The increased systemic venous return increases right atrial pressures and promotes right-to-left shunting through the foramen ovale.

Cardiac examination reveals a hyperdynamic precordium. A prominent second heart sound, S₃, and S₄ may be heard. Systolic murmurs may be present secondary to tricuspid valve regurgitation or increased flow across the pulmonary valve. Increased tricuspid valve flow may create a diastolic sound. Bruits may be heard over

• **Fig. 55.25** Surgical Repair of Interrupted Aortic Arch, Type B. (A) The branch pulmonary arteries and arch vessels are snared, and a ligature is placed around the ductus arteriosus. (B) The proximal descending aorta is controlled with a clamp. To adequately mobilize the descending aorta, the left subclavian artery may need to be divided (as shown). Following resection of the ductus arteriosus, the proximal (pulmonary artery) end is oversewn. (C) The descending aorta is anastomosed directly to the ascending aorta. An alternative strategy is anastomosis of the left subclavian and left common carotid arteries combined with homograft patch augmentation of the inferior surface of the arch. Ventricular septal defect closure, when present, is also performed (not shown). a, Artery. (From Castañeda AR, Jonas RA, Mayer JE Jr, Hanley FL. *Cardiac Surgery of the Neonate and Infant*. Philadelphia, PA: WB Saunders; 1994.)

the vascular malformation. When a malformation is suspected, care must be taken to auscultate areas where malformations are likely such as the head, liver, and chest. Arteries proximal to the malformation are typically dilated with bounding pulses, while those distal are small with diminished pulses. ECG is nonspecific and may demonstrate right atrial and right ventricular enlargement. Chest X-ray reveals cardiomegaly with increased pulmonary vascular markings. Echocardiogram demonstrates generalized cardiomegaly. Treatment, if necessary, requires interventional closure of the anomalous vascular connections or the surgical removal of associated anatomic abnormalities.

Cardiomyopathy

A large body of literature exists describing the diagnosis and management of structural CHD in the fetus and newborn. There is a paucity of information, however, regarding the diagnosis and

management of fetal and newborn cardiomyopathy. When presented with a newborn with signs of CHF, structural heart disease should be ruled out. In the absence of structural problems, the diagnosis of cardiomyopathy should be considered. The cause of neonatal cardiomyopathy includes prenatal infections (cytomegalovirus, human immunodeficiency virus, parvovirus), familial or genetic causes, maternal autoimmune disease with anti-Ro or anti-La antibodies, prenatal drug exposure, arrhythmia-induced cardiomyopathy, and twin-twin transfusion syndrome. Postnatal evaluation should include a search for the cause.

Initial management is similar to that used for other types of heart disease. Initial stabilization may require mechanical ventilation, the use of inotropes, afterload reduction, and diuresis. Long-term treatment is dependent somewhat on the cause of the cardiomyopathy, as some forms may be reversible. Cardiac transplantation should be considered if cardiac function is poor or improvement is not noted.

Perinatal Arrhythmias

TERRENCE CHUN AND BHAWNA ARYA

KEY POINTS

- The term *supraventricular tachycardia* (SVT) encompasses several different arrhythmias that may have different diagnostic and therapeutic requirements.
- Tachycardia mechanisms may be caused by conduction reentry, enhanced automaticity, or triggered automaticity.
- Isolated atrial and ventricular ectopy are common in the fetus and neonate and usually do not require any therapy.
- Congenital forms of complete heart block may result in slow heart rates but may not require pacemaker implantation.
- Fetal arrhythmias are rare but when present can result in significant hemodynamic compromise.
- Management of fetal arrhythmias is complex and involves evaluation of multiple factors, including: (1) severity of rhythm abnormality, (2) fetal comorbidities and signs of heart failure, (3) maternal comorbidities, and (4) gestational age at diagnosis.

The cardiac conduction system in the normal human heart enables a synchronized and orderly activation of the myocardium and chambers to provide optimal cardiac output. This sequence begins even in the earliest stages of cardiac development. However, disorders of cardiac rhythm can occur at any stage of life, from the fetus to the infant to the adult. These can range from transient and mild disturbances in rhythm to recurrent or persistent arrhythmias that can have significant hemodynamic consequences. Some abnormalities, such as isolated atrial or ventricular ectopy, can be more bothersome to the care provider than to the patient. Other disturbances, such as incessant tachyarrhythmias, can progress to heart failure and hemodynamic collapse. While the incidence of cardiac arrhythmias is increased in the setting of congenital heart disease (CHD), many of these abnormalities are commonly seen in the setting of an otherwise structurally normal heart. Knowledge of the spectrum of cardiac rhythm disturbances is important for prompt recognition, referral, and management. In this chapter, the etiology and common mechanisms of various arrhythmias, as well as differential diagnosis and treatment strategies, will be discussed in separate sections. The unique issues surrounding the diagnosis and management of arrhythmias in the fetus will also be addressed.

Conduction System of the Human Heart

To properly understand the mechanisms of arrhythmogenesis, it is important to recognize the core elements of the normal cardiac conduction system. The embryogenesis of the heart and the conduction system are beyond the scope of this chapter. However, the components of the cardiac conduction system are relatively set by the second trimester of gestation and provide the substrate for many of the observed arrhythmias ([Moorman et al., 2005](#)).

Sinus Node

The sinus node resides in the area between the vena cava and the right atrium and is predominantly located near the superior vena cava to right-atrial junction ([Christoffels et al., 2010](#)). However, there is no anatomic feature that is visible on gross inspection. Functional electrophysiology testing studies and animal studies have demonstrated that the nodal tissue can span the lateral wall of the right atrium, extending from the superior vena cava to the inferior vena cava.

The sinoatrial nodal tissue is histologically distinct from the atrial myocardium and has no contractile components. Electrical impulses are generated by automatic action potential behavior. Activation of the adjacent atrial myocardium by the sinus nodal tissue results in a wave of depolarization that propagates by cell-to-cell activation in a superior-to-inferior and a right-toward-left (in the structurally normal heart) fashion.

Atrioventricular Node

The atrioventricular (AV) node is a more organized area of conduction in the right atrium near the crux of the heart. More well-defined than the sinus node, the compact AV node is located in the posterior portion of the interatrial septum just anterior to the tricuspid valve and (in most cases) provides a singular conduction channel into the bundle of His and the distal conduction system ([Moorman et al., 2005](#)).

The majority of the atrial propagation wave depolarizes the mass of the atria. However, impulses that reach the area of the AV node enter the transition zone of conduction “input” into the AV node. Overall conduction velocity is slowed through the compact AV node but then exits the node into the specialized conduction fibers of the His–Purkinje system.

His–Purkinje System

In the normal heart, the atrial and ventricular myocardium are electrically isolated from each other by the AV rings (tricuspid and mitral annuli). The penetrating bundle of His is usually the only conductive tissue that traverses the AV rings into the ventricles. The bundle of His is insulated from ventricular myocardium until it gives off branches. The first branch from the His bundle enables activation of the septum. Next, the bundle bifurcates into the right- and left-bundle branches. The left bundle divides into anterior and posterior fascicles. At the terminus of each of these bundle branches, the specialized conduction tracts fan into an intricate network of short Purkinje fibers that insert into numerous sites on the ventricular myocardium. Electrical impulses that are conducted through the His–Purkinje system result in activation of the ventricular myocardium in a highly organized and synchronized fashion, translating into a mechanically efficient contraction of both left and right ventricles almost simultaneously.

Abnormalities in Cardiac Conduction

When the normal sequence of cardiac activation is disturbed, the result can be an irregularity in the cardiac rhythm. However, in many cases these disturbances will only be detected on electrocardiography or rhythm monitoring and have no manifestations on physical examination or otherwise. AV block can occur at any level of the conduction pathway if anything impedes propagation of the impulse through that conduction segment. This can be functional (because of negative vagal stimulation) or anatomic (as can be seen following cardiac surgery).

First-Degree Atrioventricular Block

Any conduction delay that prolongs the PR interval beyond the normal range for age is considered a first-degree AV block. By definition, impulses must still be conducted such that a 1:1 AV relationship persists. In the neonate the normal PR interval is generally between 80 and 120 ms, up to 140 ms in the first few months of life, and up to 160 ms in the first 6 months of life (Davignon et al., 1980). In general, first-degree AV block is benign and does not require any special treatment. It can be a normal variant or may be the result of influences that prolong the overall conduction time through the AV node and His–Purkinje system. Increased vagal tone is a common cause of PR prolongation. In the newborn, this can be a manifestation of vagal stimulation caused by a nasogastric or orogastric tube stimulating the oropharynx. More pathologic causes of PR prolongation can include neonatal lupus syndrome or myocarditis. Although there is evidence that significant PR prolongation has a negative impact on cardiac output in the adult heart, there is no indication that this is true in the neonate with a structurally and functionally normal heart. Even when the PR interval is extremely prolonged, there is usually no hemodynamic impact, and the cardiac examination remains essentially unchanged.

Second-Degree Atrioventricular Block

Second-degree AV block is ascribed when there is incomplete conduction from the atrium to the ventricle; that is to say, not every P wave is conducted to a QRS complex. This usually manifests as a skipped beat on physical examination or on cardiac monitoring. Mobitz type I conduction block, also known as *Wenckebach pattern*,

describes a pattern wherein the AV conduction becomes progressively prolonged with each successive beat. The PR interval becomes gradually longer and after a number of beats (usually two or three, although this can certainly be longer) there is failure to conduct for a single beat. The subsequent P wave is then conducted with a normalized PR interval, and the cycle begins anew. Mobitz type II conduction block is present when there is cyclical lack of conduction; however, the progressive PR prolongation seen in the Wenckebach pattern is lacking. Mobitz type I conduction can be seen in conditions of increased vagal tone (as described previously), whereas Mobitz type II is practically unheard of in the neonate in the absence of any other heart disease.

Third-Degree Atrioventricular Block

Third-degree, or complete AV block, occurs when there is complete lack of conduction between the atria and the ventricles. In most situations of complete AV block, there is an escape depolarization mechanism, either junctional or ventricular in origin, which ensures that cardiac output is maintained. Complete AV block can be congenital or acquired. Congenital complete AV block is a particularly challenging entity and is described in a subsequent section. The most common causes of acquired complete heart block are infections or neonatal myocarditis. In addition, acquired complete heart block can occur as a complication of neonatal cardiac surgery in 1%–3% of cases that involve surgical intervention near the interventricular septum (Gross et al., 2006).

Ventricular Preexcitation

Ventricular preexcitation occurs when the ventricular myocardium is activated abnormally, usually by an accessory bypass tract. The ventricular depolarization pattern is thus a combination (fusion) of early activation of a portion of the ventricles through an accessory pathway, and the remainder of activation occurring via the normal His–Purkinje system. In general, these bypass tracts bridge the AV groove that typically separates the atria from the ventricles and result in an anomalous electrical connection to the ventricles.

There are three electrocardiographic features that define this “Wolff–Parkinson–White” pattern: (1) short PR interval, (2) a slurred “delta wave,” and (3) widened QRS duration. How evident this pattern is on electrocardiogram (ECG) can vary depending on the location of the accessory pathway (and thus how early the preexcited portion is activated) and how quickly the ventricles are also activated by the His–Purkinje system. In the newborn heart, the rapid transit time through the AV node and His–Purkinje system can result in a very minimal amount of preexcitation being evident, and appreciation of the presence of the Wolff–Parkinson–White pattern can be delayed, sometimes for years (Cain et al., 2013). Usually, this diagnosis is made only when the newborn patient experiences a tachyarrhythmia (as discussed later).

Abnormalities in Cardiac Rhythm

Alterations in the normal cardiac rhythm can occur by one of several mechanisms and sometimes in combination. These include: (1) enhanced automaticity, (2) reentry mechanisms, and (3) triggered automaticity.

Certain areas of the heart have a tendency to exhibit spontaneous automaticity, such as the sinus node and the AV junction. Sometimes an abnormal cluster of cells can have a particular tendency toward this behavior. Gradual depolarization of the tissue during phase 0

of the action potential (electrical diastole) eventually crosses the action potential threshold, resulting in the depolarization–repolarization sequence, after which it returns to electrical diastole until the gradual depolarization occurs again (Moorman et al., 2005). After the action potential begins in the abnormal ectopic focus, the adjacent myocardium is also depolarized, which then propagates a wavefront outwards from that locus. Automatic rhythms tend to exhibit “warm-up” and “cool-down” behavior, gradually (although sometimes briskly) accelerating and then decelerating back to normal. Even when persistent, there tends to be beat-to-beat variability, and the rate can also be influenced by external influences such as autonomic tone, metabolic states, or hormonal influences. In addition, automatic rhythms can be “overdrive” suppressed when driven by a faster rhythm from another source.

Triggered automaticity occurs when excitable tissue spontaneously depolarizes to the activation threshold, beginning an action potential in that cell or cells that is then perpetuated to the adjacent myocardium. This can occur in fairly normal tissue but can be particularly enhanced by conditions of acidosis, mechanical stimulation, myocardial injury, or inflammation. Increased automaticity is often observed in the presence of certain drugs, such as inotropic medications like dopamine or epinephrine, or stimulant medications like caffeine.

Reentry rhythms are some of the more instantly recognizable tachyarrhythmias in the neonate and young infant. In contrast to the gradual nature of automatic rhythms, reentry has a very abrupt onset and termination. During the rhythm, the rate tends to be fairly stereotyped and consistent. Reentrant rhythms require several prerequisites to perpetuate. First, there must be an arrhythmia “circuit” present with both antegrade conducting and retrograde conducting limbs. Next, there must be differential conduction between the limbs of the arrhythmia circuit, whereupon one limb must exhibit slowing or unidirectional block. Finally, all elements of the arrhythmia circuit must be able to support a repetitive rhythm at a fixed rate.

Ectopic Beats

Premature Atrial Complexes

Isolated atrial ectopy is commonly seen in children and, in particular, during the newborn period. There are no ethnic predilections toward ectopy. Premature atrial complexes can be observed during fetal monitoring and have been reported to occur in up to 25%–50% of normal newborns (Nagashima et al., 1987); however, in the vast majority of cases, this resolves within the first few months of life. Premature atrial complexes are caused by an early triggered depolarization of the atria from an ectopic focus that is separate from the sinus node. On surface ECG this manifests as a P wave that is earlier than would be expected from the preceding rhythm, and the ectopic P wave has a very distinct axis and morphology from the normal sinus P wave. In this manner, one can differentiate the premature atrial complex as originating from a location separate from the sinus node.

Most atrial ectopy in the neonate is conducted normally, meaning that the premature atrial complex is followed by a normal-appearing QRS complex. The PR interval may be measured as different to normal, which is more a reflection of the atrial depolarization beginning in an abnormal location (and thus either closer or further than the sinus node) rather than indicating any defect in AV conduction. When a premature atrial complex is closely coupled to the preceding beat, the conducted QRS complex may have an abnormal appearance. This “aberrant conduction” may just be

slightly wider than normal or it may have the appearance of a complete bundle branch block. This is caused by the early impulse failing to conduct, as the refractory period for that segment has been exceeded. Aberrantly conducted premature atrial complexes are often mistaken for premature complexes because of their wider appearance but can be distinguished by the presence of a preceding P wave. Blocked premature atrial complexes can occur if the ectopic beat occurs early enough after the preceding beat. While this effect is more pronounced where this is impaired AV conduction, it is most commonly observed in the setting of normal nodal conduction and results from the early atrial impulse failing to conduct because of the refractory period of either the AV node or the His–Purkinje system. Blocked premature atrial complexes are identified by the presence of the ectopic P wave (usually with the T wave of the preceding beat) that has no QRS complex following. Often, there will be a sinus pause before the next normally conducted sinus return beat. In most instances, isolated premature atrial complexes in the newborn do not require any treatment.

Premature Ventricular Complexes

Isolated ventricular ectopy is also commonly observed in the normal neonate, although to a lesser extent than atrial ectopy (Nagashima et al., 1987). Ventricular ectopic beats are usually distinguished by a widened QRS complex with a T-wave axis that is different when compared with the normal QRS–T complex. Importantly, there is no P wave that precedes the premature QRS complex. In isolation, ventricular ectopy has no pathologic implications for infants who have no other signs or symptoms to suggest any cardiac pathology.

Tachyarrhythmias

While a number of tachyarrhythmias can be observed during childhood, only a subset of distinct arrhythmias is observed with any frequency in the fetus and neonate (Table 56.1). The most common of these are orthodromic reciprocating tachycardia (ORT), atrial ectopic tachycardia, and atrial flutter.

Orthodromic Reciprocating Tachycardia

ORT is the most common form of supraventricular tachycardia (SVT) in the fetus and the neonate (Spearman and Williams,

TABLE 56.1

Differentiating Neonatal Tachyarrhythmias

| VA Relationship | Differential Diagnosis |
|--------------------|---|
| A > V | Atrial ectopic tachycardia Atrial flutter |
| Short VA (VA < AV) | ORT (SVT) JET (VA-associated) |
| Long VA (VA ≥ AV) | Sinus tachycardia Atrial ectopic tachycardia PJRT |
| V > A | Ventricular tachycardia JET (VA-dissociated) |

A, Atrial activity; AV, atrioventricular; JET, junctional ectopic tachycardia; ORT, orthodromic reciprocating tachycardia; PJRT, permanent form of junctional reciprocating tachycardia; SVT, supraventricular tachycardia; V, ventricular activity; VA, ventriculoatrial.

2014). It is the arrhythmia mechanism most commonly associated with SVT, so the terms are often used interchangeably. The tachycardia circuit for this reentrant arrhythmia utilizes the normal conduction system as the antegrade limb, and an accessory pathway provides the retrograde limb for the tachycardia (Fig. 56.1). When conditions are appropriate, impulses conducted through the His–Purkinje system to the ventricles are then carried in a retrograde fashion over an accessory pathway to the atria, which then reaches the AV node to start the cycle again. If not in their refractory periods, the atria, AV node and His–Purkinje system, ventricles, and accessory pathway all perpetuate a rapid repetitive SVT rhythm. In the fetal and neonatal heart, this form of SVT will manifest with very fixed rates that typically range between 240 and 300 beats per minute (bpm). So-called *retrograde* P waves may be visible on the ST segment or the T wave, as evidence of the conduction time between the activation of the ventricles, passage through the accessory pathway, and subsequent reactivation of the atria. The measured RP interval can be used to aid in the differential diagnosis of the various forms of SVT, which can consequently be used to help guide specific management and for prognosis.

When an accessory pathway only conducts in a retrograde direction it is called a *concealed* accessory pathway; that is to say, there is no evidence of pathway conduction during normal sinus rhythm conditions, and the pathway only conducts from ventricle to atrium during reciprocating tachycardia. A manifest accessory pathway is one whose presence is known during normal sinus rhythm. These are the pathways that cause the ventricular preexcitation of Wolff–Parkinson–White syndrome (discussed previously). Manifest pathways usually conduct bidirectionally; antegrade conduction results in preexcitation on resting ECG, and retrograde conduction is utilized during reciprocating tachycardia, resulting in a narrow QRS complex without preexcitation (Fig. 56.2).

For the neonate on continuous heart rate monitoring in the intensive care unit, such episodes of SVT are usually quite apparent

by the abrupt onset and spontaneous termination of a rapid heart rate. In the absence of any monitoring the development of SVT may not be as obvious. In contrast to older children who are able to report complaints of palpitations, neonates and young infants rarely give any indication of the tachyarrhythmia occurring within. Sometimes, pallor, diaphoresis, or a change in respiratory pattern

• **Fig. 56.1** Mechanism for Orthodromic Reciprocating Tachycardia. Antegrade conduction through His–Purkinje system depolarizes ventricles. • **Fig. 56.2** Wolff–Parkinson–White Syndrome. Spontaneous termination of orthodromic reciprocating tachycardia. Note change from narrow QRS in tachycardia, then wide preexcited QRS during subsequent sinus rhythm.

may be evident to the outside observer. However, despite the rapid rates, SVT is generally well tolerated. Most episodes of ORT are self-limited, persisting only for seconds or minutes at a time; sometimes, episodes can last 30–60 minutes or more before terminating spontaneously. In rare instances the SVT can be incessant, lasting for hours or sometimes a day or more. In these cases, delay in recognition and diagnosis can lead to a tachycardia-induced dilated cardiomyopathy and can possibly result in eventual cardiovascular collapse.

Acute management of ORT is directed at terminating the tachycardia and restoration of sinus rhythm. Slowing or transient blockade of AV nodal conduction is the mechanism by which most therapies work and includes vagal maneuvers (such as knee-chest position or diving reflex) and administration of adenosine. Initial adenosine doses of 0.05–0.1 mg/kg by rapid intravenous (IV) bolus are recommended for the neonate, with escalating doses as necessary. Direct current cardioversion for immediate arrhythmia termination can also be considered for the infant with impending collapse, although the risks versus benefits of this approach must be considered. For chronic medical therapy in the infant prone to recurrent episodes of SVT, β -blockade in the form of propranolol is often used as a first-line agent. In some institutions, digoxin is used alone or in combination with propranolol. While calcium channel blockers are readily used in older children and adults for this indication, this class is generally avoided in the young infant due to the potential for significant myocardial depression. Second-line agents include sotalol, flecainide, and amiodarone. These medications are discussed further in the Management Considerations for Neonatal Tachyarrhythmias section later.

Permanent Form of Junctional Reciprocating Tachycardia

An unusual but particular vexing variant of ORT is the permanent form of junctional reciprocating tachycardia (PJRT). This is a reentry form of SVT that has rates that are usually far slower than the usual form of ORT, sometimes seemingly at the upper limits of the normal range for the newborn, around 180–200 bpm.

However, PJRT has a tendency toward being an incessant arrhythmia, often spontaneously reinitiating immediately after tachycardia termination. The mechanism for PJRT is usually a concealed accessory pathway, typically located in the posterior septum or posterior tricuspid annulus. The conduction velocity of this retrograde limb is slower than in most other types of accessory pathways, resulting in a very long RP interval. Another hallmark feature is the presence of strongly negative retrograde P waves in the inferior leads, particularly lead II (Fig. 56.3). These infants often escape early detection as the tachycardia rates are not dramatically elevated, which can lead to delayed diagnosis and presentation with tachycardia-induced cardiomyopathy or congestive heart failure (Kang et al., 2014). Treatment can be challenging as the arrhythmia has a tendency toward spontaneous reinitiation, even after successful termination of tachycardia. Medical therapy includes the drugs described above, although most infants with PJRT will require multiple agents for successful control of this arrhythmia.

Atrial Ectopic Tachycardia

Atrial ectopic tachycardia (AET) is a less common cause of SVT than ORT but is still well-represented among perinatal tachyarrhythmias. This is also known by other monikers such as *ectopic atrial tachycardia* or *focal atrial tachycardia*. In contrast to the reciprocating tachycardias, AET is not caused by a bypass tract but rather by a focus of cells in the atria that are more excitable than the sinus node and exhibit enhanced or triggered automaticity. As atrial activation originates from a location other than the sinus node, the P waves on surface ECG are usually quite distinctly different to normal (Fig. 56.4). The result is paroxysmal bursts of tachycardia, although prolonged and even incessant tachycardia can also be seen, which can lead to the development of tachycardia-induced cardiomyopathy (Gopinathannair et al., 2015). This arrhythmia is often catecholamine-sensitive, with increased clinical signs during periods of activity or stimulation. Heart rates often vary during sustained tachycardia, and the rates can range from slightly faster than sinus rhythm to well over 300 bpm at times. Since the tachycardia does not depend on intact AV nodal

• **Fig. 56.3** Permanent Form of Junctional Reciprocating Tachycardia. Typical appearance of permanent junctional reciprocating tachycardia, with long ventriculoatrial time (ventriculoatrial > atrioventricular) and strongly negative P waves in inferior leads II, III, and aVF.

• **Fig. 56.4 Atrial Ectopic Tachycardia.** P waves with unusual axis “march through” the tracing, with more P waves than QRS complexes on tracing. Wide aberrantly conducted QRS complexes are caused by “Ashman phenomenon” of conduction.

conduction, intermittent AV block (such as 2:1 conduction or Wenckebach pattern) can sometimes be seen, and this feature is often used to aid in the correct diagnosis. By the same token, nodal blockade does little to affect this arrhythmia. Adenosine administration usually only transiently blocks the AV nodal conduction while the atrial arrhythmia continues unabated. While direct current cardioversion may interrupt the arrhythmia, it is likely to reinstate spontaneously, because of its paroxysmal nature.

Junctional Ectopic Tachycardia

Another automatic supraventricular arrhythmia of childhood is junctional ectopic tachycardia (JET). This is caused by increased automaticity of the cells around the AV junction resulting in direct activation of the His–Purkinje system. Heart rates range from 170 to 210 bpm and demonstrate the usual warm-up and cool-down behavior. The atrial activity may be conducted retrograde from the junctional activity or may be completely dissociated from it. JET can be either acquired or congenital. The acquired form can occur in up to 20% of patients following cardiopulmonary bypass for certain congenital cardiac surgeries (Moak et al., 2013) and can cause hemodynamic embarrassment because of the inherently unstable nature of those patients, even though the arrhythmia itself is fairly self-limited. The congenital form of JET is quite rare but like atrial tachycardia can be an incessant arrhythmia. Such patients can present with tachycardia-induced cardiomyopathy (Gopinathannair et al., 2015).

Neonatal Atrial Flutter

Atrial flutter is a macro-reentrant arrhythmia that occurs entirely within the atria, with a depolarization wavefront that typically runs in a counterclockwise direction around the tricuspid valve

annulus. The atrial rate is usually 300 bpm or greater, and the continuous atrial activation gives it a characteristic “sawtooth” pattern in the inferior leads, particularly lead II and III (Fig. 56.5). The atrial rate is exceedingly consistent and entirely independent of the ventricles, although varying degrees of AV conduction can be observed. While older infants and children might conduct every other (2:1) or every third (3:1) atrial impulse, the neonatal AV node has brisker conduction capability so may conduct each impulse (1:1), resulting in a very rapid ventricular rate. Administration of adenosine can be diagnostic by blocking AV nodal conduction while the flutter waves continue uninterrupted.

Medical therapy may be used to slow the ventricular rate. However, in most cases direct current cardioversion is required; this is highly effective and the recurrence risk is low (Casey et al., 1997). In the fetus there is often 1:1 conduction with a very rapid ventricular rate. When undetected and untreated, this can result in congestive heart failure, which manifests as hydrops fetalis. Detection and diagnosis may be difficult as it is unusual to be able to obtain a rhythm recording or ECG. A fetal echocardiogram may be able to demonstrate rapidly contracting atria (as discussed later). When necessary, fetal flutter may be treated by administering antiarrhythmic medications to the mother, although high maternal doses are often required to achieve adequate transplacental transfer to the fetus.

Ventricular Tachycardia

Ventricular tachycardia (VT) is a fairly uncommon arrhythmia in the perinatal period. It can take varied forms, ranging from a benign accelerated ventricular rhythm to a potentially life-threatening polymorphic VT. The latter is rarely encountered and occurs only in the setting of severe metabolic derangements or electrolyte disturbances or in the setting of an underlying congenital primary

• **Fig. 56.5** Atrial Flutter. The atrial rate is approximately 360 beats per minute, with “flutter waves” visible in leads II, III, and aVF. Note that not all flutter P waves conduct equally to the number of QRS complexes.

arrhythmia syndrome. VT may be suspected on the basis of a wide QRS complex tachycardia, although the differential diagnosis of such a rhythm includes a supraventricular rhythm conducted aberrantly, such as with preexcitation pattern (as discussed earlier) or when conducted with a bundle branch block. However, in most instances, monomorphic VT is generally a benign entity in infancy and rarely requires intervention other than medical therapy (Levin et al., 2010).

Accelerated idioventricular rhythm (AIVR) is a benign arrhythmia. Sometimes considered as “slow VT,” AIVR is caused by enhanced automaticity of the ventricles and is usually due to intrinsic catecholamine states, electrolyte disturbances, or other conditions that predispose to increased automaticity. The hallmark is a monomorphic rhythm that originates in the ventricles but at rates that are only slightly faster than the normal sinus rates. This is generally well tolerated hemodynamically, unless the infant is otherwise extremely compromised by other medical factors.

In contrast to the stability of monomorphic ventricular arrhythmias, polymorphic VT is a much more disorganized and potentially life-threatening arrhythmia and must be recognized and managed emergently. The ECG in polymorphic VT exhibits a rapid wide QRS complex, and the QRS morphology varies from beat-to-beat, indicating generally disordered ventricular depolarization. Cardiac output can be severely reduced. A particular variant of polymorphic VT is known as *torsades de pointes* (TdP). Literally, “twisting about a point,” the amplitude and axis of the QRS morphology rotate and undulate and can eventually degenerate into a more chaotic ventricular fibrillation. It is rarely seen in the neonate, except in the setting of primary arrhythmia genetic syndromes that are

associated with sudden cardiac death, such as the long QT syndrome (LQTS) (as discussed later).

Management Considerations for Neonatal Tachyarrhythmias

Appropriate treatment of neonatal tachyarrhythmias depends largely upon prompt recognition and accurate diagnosis. The most common substrates for tachycardia in this subset are ORT and AET, in addition to neonatal flutter. Orthodromic tachycardia can acutely respond to vagal maneuvers and (more reliably) to IV adenosine administration, although these methods will have little to no effect on either AET or neonatal flutter. Because of the increased likelihood of recurrent reentry tachycardia during early infancy, medical therapy is commonly utilized to decrease the possibility. Many infants can show no outward signs that they are experiencing tachycardia until incessant tachyarrhythmias result in a dilated cardiomyopathy and cardiovascular collapse. Older infants and children will usually give more outward signs of being in a tachyarrhythmia, so are less likely to present with cardiomyopathy and cardiovascular collapse.

Medical therapy for neonatal tachycardia varies considerably across institutions (Seslar et al., 2013). Digoxin selectively inhibits the sodium-potassium adenosine triphosphatase channel, which causes an increased intracellular sodium concentration. Other cardiac effects include a positive inotropic effect and an increased vagotonic effect. It is this latter effect that is suspected to contribute to the antiarrhythmic properties of the drug. In many institutions,

digoxin was historically used most commonly for acute and chronic management of SVT, although its utilization varies greatly (Guerrier et al., 2016).

Propranolol (Vaughan-Williams class II) is a nonspecific β -blocker medication that binds β -adrenergic receptors. This decreases overall sensitivity to adrenergic stimulation and has some direct effects on myocyte membrane potential. While the overall success of propranolol versus digoxin is comparable (Moffett et al., 2015), digoxin was less likely to succeed initially as monotherapy. In addition, digoxin is contraindicated in the Wolff–Parkinson–White syndrome because of enhancement of accessory pathway conduction properties, so ventricular preexcitation must be excluded before initiation of digoxin. The drug is also generally ineffective for AET. Enteral propranolol is increasingly used as first-line therapy for neonatal SVT, preferentially in high-volume treatment centers (Guerrier et al., 2016). Particularly in the preterm newborn, the risk of β -blocker-associated hypoglycemia exists so monitoring of blood glucose during initiation of propranolol therapy is recommended in this population.

Second-line agents include flecainide and sotalol, as well as amiodarone, and are highly effective in controlling the arrhythmia in incessant forms of neonatal SVT (Price et al., 2002). These drugs require closer monitoring because of their proarrhythmic effects. All three can potentially prolong the QT interval and potentially provoke ventricular arrhythmias. Flecainide (Vaughan-Williams class Ic) inhibits the fast inward sodium current of the myocardial action potential and prolongs conduction through all cardiac tissues, particularly those of the His–Purkinje system and ventricular myocardium. This can result in decreased ability of the conduction system to perpetuate SVT and is a very effective drug for treating SVT. Flecainide is bound by milk protein and significant fluctuation in drug serum levels has been reported in neonates transitioning to oral feeds (Russell and Martin, 1989); it can also prolong the QRS complex.

Vaughan-Williams class III medications used to treat perinatal SVT include sotalol and amiodarone. This class of drugs prolongs the action potential duration by extending the repolarization phase of the myocardium, thus increasing the overall refractory period of the tissue. This decreases the ability of the myocardium to support the repeated depolarizations necessary to support SVT. Sotalol exhibits β -blocker effects (class II) in lower doses and in higher doses exhibits more class III effects. Amiodarone is highly effective for acute and chronic management of tachyarrhythmias in the neonate; however, it must be used judiciously as it can have the effect of hypotension, bradycardia, heart block, cardiovascular collapse, and hypothyroidism. It has been reported to cause “neonatal gasping syndrome” and to leach plasticizers from polyvinyl chloride containers and syringes (Centers for Disease Control and Prevention, 1982). Because of the pharmacokinetics of amiodarone, it is usually administered by loading doses (in both IV and enteral dosing) for 7–10 days, after which the dose is decreased to a maintenance dose.

While commonly performed in older children, percutaneous catheter ablation for supraventricular arrhythmias is rarely performed in neonates and small infants. Technical issues and catheter size limit conventional mapping and ablation techniques. Late complications and deaths caused by injury to adjacent coronary artery structures have also been reported (Al-Ammouri and Perry, 2006).

While most ventricular arrhythmias in the neonate are controllable and self-limited, certain conditions may predispose to more life-threatening forms of VT. Particularly in cases in which defibrillation must be performed, for hemodynamically unstable VT or ventricular fibrillation, additional therapies must be considered.

Reversible causes of TdP such as electrolyte disturbances or drug-induced TdP should be addressed by aggressive correction of the imbalance or removal of the offending agent(s). However, when no such cause can be identified, the etiology is often found to be a congenital arrhythmia syndrome, commonly LQTS (as discussed later). In more-affected infants, treatment with β -blocker medications may be used, and in severe cases with recurrent episodes of TdP or ventricular fibrillation in which the anticipated risk of sudden cardiac arrest is excessive, implantation of a pacemaker or a defibrillator might be considered; however, this must be weighed against the acute implantation issues and longer-term complications.

Bradyarrhythmias

Neonatal forms of bradycardia are few. In general, bradycardia is defined as sustained heart rates less than 100 bpm. This can be the result of normal physiologic causes or secondary to arrhythmias or abnormalities in conduction. Sinus bradycardia represents the most common mechanism in the neonate. This can be a normal physiologic variant (it is not uncommon to encounter a normal term neonate with a sinus rate of 90 bpm in the first 24–48 hours after birth, especially during sleep) or secondary to other causes (such as therapeutic hypothermia). Another common mechanism is vagal stimulation, which can be provoked by the presence of oral or nasal feeding tubes, endotracheal tubes, or episodes of gastroesophageal reflux.

Blocked Premature Atrial Complex

Atrial ectopy is commonly encountered in the fetus and newborn (discussed previously). In most instances, the premature atrial complex (PAC) conducts normally to a normal-appearing QRS complex. However, PACs that occur earlier in relation to the preceding QRS complex may find the conduction system or ventricular myocardium refractory to stimulation. Thus the PAC is not followed by any ventricular depolarization. This is described as a “blocked PAC.” Most often, this is observed when a PAC occurs in the early portion of the preceding T wave, such that the ventricles are still in their refractory period and cannot depolarize. Conditions that affect the refractoriness of either the AV nodal conduction or myocardial refractoriness, such as increased vagal tone or metabolic acidosis, can also increase the likelihood that a PAC is blocked. Following the premature atrial depolarization, there is typically a delay before the subsequent sinus return beat. When atrial ectopy is frequent, as in blocked atrial bigeminy, the net effect is a functional “halving” of the sinus rate (Fig. 56.6).

Long QT Syndrome

In severe forms of congenital LQTS the QT prolongation can result in bradycardia in the fetus or the newborn. When the repolarization phase becomes significantly prolonged, the subsequent sinus P wave may fail to conduct normally or at all as the ventricular myocardium is still refractory to stimulation. As a result, the functional heart rate is halved since the ventricular rate is conducted 2:1 from the sinus rate. This can have significant implications as the bradycardia may not be tolerated by the patient. Chronotropic medications for this condition may do little to improve the functional heart rate as increasing the frequency of sinus P waves does not shorten the refractory period of the ventricular myocardium. Permanent pacemaker implantation may be necessary. In addition, the functional

• **Fig. 56.6** Premature Atrial Complexes. Premature atrial complexes occurring on ST segments are failing to conduct to ventricles resulting in “blocked atrial bigeminy.”

• **Fig. 56.7** Long QT Syndrome With 2:1 Functional Heart Block. The sinus rate is 110 bpm. The QT interval is profoundly prolonged ($QT_c = 751$ ms), so every other sinus P wave cannot conduct because of the ventricular refractory period.

nature of this “2:1” heart block can result in irregularities in the conduction pattern (Fig. 56.7). This can result in profound QT prolongation as well as triggering VT and TdP.

Congenital Complete Atrioventricular Block

Congenital complete AV block (CCAVB) is the absence of AV conduction. This is rather uncommon, occurring in only 1 in 15,000 to 1 in 20,000 births (Bordachar et al., 2013). It is commonly associated with maternal lupus, although it also occurs in the absence of any known maternal disease. Fetal exposure to maternal autoantibodies (most commonly anti-SSA/Ro and anti-SSB/La antibodies) results in fibrosis of the AV nodal structures, leading to a progressive destructive process. There is some evidence that early treatment with high-dose maternal steroids could delay

or even arrest this process (Jaeggi et al., 2004); however, subsequent studies have not been able to demonstrate an improvement in conduction in treated fetuses (Fesslova et al., 2009; Hayashi et al., 2009), so the risk–benefit ratio of this therapy must be weighed on an individual basis. When detected, the fetus is monitored frequently for the development of hydrops fetalis, a sign of congestive heart failure in the fetus.

Complete heart block can also occur in the fetus or newborn in the setting of CHD, most commonly those defects that involve “L-transposition of the great arteries” or “ventricular inversion.” In these conditions, fetal looping of the heart results in the His bundle being a far more superficial structure than normal and therefore prone to fibrosis. Development of complete heart block in this setting can occur at any stage of development and often does not occur until later childhood or adulthood.

• **Fig. 56.8** Congenital Complete Atrioventricular Block. The sinus nodal rate is approximately 150 bpm, but there is complete atrioventricular dissociation with a junctional escape rate of 50 bpm.

In most cases of CCAVB, the region around the bundle of His remains intact and can exhibit normal properties of automaticity. This “junctional escape rhythm” typically results in a normal narrow QRS complex and ventricular contractility, despite the lack of AV conduction. It has the appearance of a normally conducted sinus beat but is completely dissociated from the sinus nodal P waves occurring above (Fig. 56.8). The escape rate in the fetus and neonate is often 60–80 bpm and can provide adequate cardiac output. There are many instances in which CCAVB is completely undetected in the newborn period and remains undetected for many years. The QRS complex may be wide (greater than 70 ms in the newborn) if there is extensive damage to the junctional region, implying that the escape rhythm arises from a location lower on the septum or from the ventricular myocardium itself.

However, a slower junctional escape rhythm, usually when the rate is below 50 bpm, is inadequate to support normal cardiac output. Signs of congestive heart failure may become manifest. In the fetal circulation, where the pulmonary vascular bed is largely bypassed by the ductus arteriosus, this will manifest as hydrops fetalis or intrauterine fetal demise. Management of the fetus with inadequate junctional escape rate and signs of poor cardiac output are addressed in the Fetal Rhythms section in this chapter. For the postnatal patient, signs of low cardiac output would include respiratory distress (with pulmonary congestion), poor perfusion, metabolic acidosis, low urine output, and frank edema. This can present a clinical challenge. Heart rate and blood pressure may be augmented by inotropic and chronotropic drip medications such as isoproterenol, epinephrine, and dobutamine. In some centers, temporary transvenous pacing may be utilized for emergent rescue, but this can be challenging because of the size disparity between commercially available temporary pacing leads and the small vessel size in this population (Doshi and Lokare, 2011). Permanent pacemaker implantation is indicated if there is evidence of ventricular dysfunction or low cardiac output in the neonate with a heart rate less than 55 bpm (or less than 70 bpm in the setting of concurrent CHD) or if there is evidence of a wide QRS complex escape rhythm (Epstein et al., 2008). Box 56.1 summarizes the absolute and relative indications for pacemaker implantation in the neonate with CCAVB.

• BOX 56.1 Indications for Permanent Pacing in Congenital Complete Atrioventricular Block

- Permanent pacemaker implantation is indicated for congenital third-degree AV block in the infant with a ventricular rate less than 55 bpm or with congenital heart disease and a ventricular rate less than 70 bpm.
- Permanent pacemaker implantation is indicated for congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction.
- Permanent pacemaker implantation is reasonable for congenital third-degree AV block beyond the first year of life with an average rate less than 50 bpm, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or are associated with symptoms due to chronotropic incompetence.
- Permanent pacemaker implantation may be considered for congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function.

AV, Atrioventricular; bpm, beats per minute.

ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices) developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons. *J Am Coll Cardiol*. 2008;51:e1–e62.

Fetal Rhythms

Fetal arrhythmias occur in 1%–2% of pregnancies, with resultant hemodynamic compromise, hydrops fetalis, and fetal demise occurring in 10% of cases (Naheed et al., 1996; Simpson, et al., 1997). The arrhythmias may develop late in the second or third trimester; this is particularly true for premature contractions, atrial tachycardias, and VTs, which often do not manifest before 25–26 weeks' gestation and in some cases only in the third trimester (van Engelen et al., 1994; Simpson et al., 1998). Fetal arrhythmias require close monitoring, as even benign rhythms may have a small risk of complications. The standard modality for prenatal evaluation of fetal arrhythmias is via fetal echocardiography, focusing on the

mechanical atrial and ventricular systoles and their relationship to one another (Fig. 56.9A,B) as a surrogate for AV synchrony/dyssynchrony (Jaeggi et al., 1998; Fouron et al., 2003; Carvalho et al., 2007). Investigation of the fetus referred for an abnormal rhythm should focus on causes of impaired AV conduction and causes of abnormal atrial or ventricular rhythms, including varying degrees of AV block, congenital LQTS, myocarditis, intracardiac tumors, and structural CHD. Differentiation between types of arrhythmia mechanism is helpful in determining the most optimal therapy and the likelihood of success of arrhythmia treatment.

Benign Arrhythmias

One of the most common reasons for referral to the fetal cardiologist is irregular fetal heart rhythms, noted in 1%–3% of pregnancies (Strasburger, 2005). The causes of these irregular rhythms are often isolated premature atrial contractions (Srinivasan and Strasburger, 2008). Rarely, they may be ventricular in origin. The vast majority of these atrial ectopic beats are benign; premature atrial contractions have a small risk (0.5%–1%) of developing into a fetal tachycardia (Wacker-Gusmann et al., 2014). However, 2% of cases may be associated with fetal LQTS, atrial flutter, and second-degree AV block (Cuneo et al., 2006).

Management of Benign Arrhythmias

The 2014 American Heart Association scientific statement for the diagnosis and treatment of fetuses with irregular rhythms (Donofrio et al., 2014) recommends that fetuses with frequent ectopic beats (bigeminy, trigeminy, or more than every 3–5 beats on average) should have a baseline fetal echocardiogram to assess cardiac structure and function and to determine the mechanism of the arrhythmia (Fig. 56.10). Medical treatment is not recommended for premature atrial contractions. If frequent ectopy continues, weekly heart rate monitoring, to assess for progression to tachycardia, should be performed in the obstetric office until it resolves. In fetuses with less frequent extra systoles, fetal echocardiogram is indicated if the irregular rhythm persists beyond 1–2 weeks or if there is difficulty differentiating a benign rhythm from a pathologic one (Donofrio et al., 2014). A postnatal ECG should be performed if an irregular rhythm is auscultated after birth.

Fetal Tachycardias

Fetal tachycardia constitutes a rare but important cause of perinatal morbidity and mortality. Sustained SVT includes ORT (70%), atrial flutter (30%), and rare tachyarrhythmias and usually occurs at rates greater than 220 bpm (Strasburger, 2005). The type of SVT can be determined using the mechanical PR interval derived from either the spectral Doppler of the mitral inflow and aortic outflow or the superior vena cava and aorta. Management for a given fetus can then be assessed based on the type of suspected SVT. VT is a much less common cause of fetal tachycardia as are chaotic or multifocal atrial tachycardia.

In general, the goal of in utero treatment of fetal tachycardias is not conversion to 100% sinus rhythm but instead to establish sufficient sinus rhythm to allow resolution of hydrops and ventricular dysfunction. Management depends on the gestational age at presentation, degree of fetal compromise, maternal conditions, and potential risks to the mother from therapy (Donofrio et al., 2014). Emergent delivery should be reserved for the hydropic fetus who exhibits persistent tachycardia refractory to medical

management (Srinivasan and Strasburger, 2008). Delivery can be considered as a primary management strategy if the fetus is near term and if delivery incurs no significantly increased risk to the neonate (Donofrio et al., 2014).

Orthodromic Reentrant Tachycardia

ORT accounts for approximately 70% of fetal tachycardias (Strasburger, 2005). It usually presents with intermittent or sustained heart rates in the range of 240–260 bpm. It is identified on fetal echocardiogram by the short RP interval (ventriculoatrial [VA] activation time), 1:1 AV relationship, and fast ventricular rate (Fig. 56.11). This rhythm results from conduction down the AV node to the ventricles and retrograde through an accessory pathway to the atrium. Generally, reentrant ORT presents between 28–33 weeks' gestation (Hornberger and Sahn, 2007). Progression to hydrops is not uncommon, with risk factors being tachycardia duration, fetal immaturity, and concurrent structural heart disease (Naheed et al., 1996; Hornberger and Sahn, 2007).

Intrauterine fetal treatment is recommended if delivery does not offer lower risk. The first-line and second-line antiarrhythmic therapy choices are controversial, as are the management strategies after initial treatment failure. The use of combination therapies presents greater risk for maternal and/or fetal complications, and thus monotherapy is recommended. Digoxin, flecainide, and sotalol as monotherapy have all been used successfully as first-line therapies for reentrant SVT (Oudijk et al., 2000; Jaeggi et al., 2011; Shah et al., 2012), though the use of digoxin is controversial because of the very small risk of atrial fibrillation with rapid antegrade conduction across an accessory pathway (Kleinman and Nehgme, 2004). There is no study to date that supports one as the superior treatment option. All three of these medications, as well as amiodarone, have also been used as second-line therapy (Donofrio et al., 2014). Amiodarone has a more significant toxicity profile for the mother and fetus and should be reserved as a third-line treatment for life-threatening arrhythmias. It should be discontinued once hydrops resolves. Verapamil and procainamide are no longer used to treat fetal tachyarrhythmias (Donofrio et al., 2014). Transplacental transfer of drugs is reduced in the setting of hydrops, thus direct fetal treatment (to the fetal buttock/thigh or intracordal) concomitantly with transplacental therapy has been described for restoration of sinus rhythm. These strategies should be limited to severely hydropic fetuses who cannot be delivered because of early gestational age, as there is an associated risk of fetal death (Hansmann et al., 1991; Cuneo and Strasburger, 2000).

After delivery, up to 50% of reentrant SVT cases will not have postnatal recurrence (Naheed et al., 1996). Thus medical treatment must be reassessed relative to the length of time since the last occurrence and the mechanism of clinical tachycardia.

Atrial Flutter

Atrial flutter accounts for approximately 30% of fetal tachycardias (Strasburger, 2005). It is associated with fetal myocarditis, structural CHD, and in utero exposure to SSA/SSB antibodies. It is typically characterized by atrial rates of 300–500 bpm and slower ventricular rates (150–170 bpm) because of a physiologic block in the AV node. It is best identified on fetal echocardiogram using an M-mode across an atrial free wall, interventricular septum, and ventricular free wall (Fig. 56.12). Atrial flutter is more likely to present later in pregnancy than reentrant SVT, at around 31–34 weeks' gestation. It is generally a well-tolerated rhythm because of the lower

• **Fig. 56.9** Fetal echocardiogram performed from a coronal view of the fetus demonstrating a four-chamber view of the heart with normal fetal heart rate (146 beats per minute) with 1:1 atrioventricular conduction via (A) normal mitral valve inflow and aortic valve outflow spectral Doppler. The measurement between the inflow and outflow is the PR interval (XX and ++ = 116 ms). (B) M-mode diagonally across the four-chamber heart measures the movement of the atrial (A) and ventricular (V) free wall. *bpm*, Beats per minute; *HR-AV*, heart rate measured from aortic valve Doppler.

• **Fig. 56.10** M-mode of the Fetal Heart Demonstrating an Isolated Premature Atrial Contraction. There is normal atrioventricular conduction at a normal rate until the fifth labeled atrial beat (A) that is early (ectopic) and results in a blocked ventricular beat (V).

• **Fig. 56.11** Fetal Mitral Inflow and Aortic Outflow Spectral Doppler Demonstrating Reentrant Supraventricular Tachycardia. There is 1:1 atrioventricular conduction (A and V labels) at a steady rate of 238 beats per minute. The RP interval is 100 ms.

• **Fig. 56.12** M-mode of the fetal heart demonstrating 2:1 atrial flutter with an atrial rate of 120 beats per minute and a ventricular rate of 260 beats per minute. A, Atrial flutter waves; V, ventricular activation.

ventricular rates (Jaeggi et al., 1998; Strasburger, 2005). However, the rhythm can remain undiagnosed prenatally because of the relatively normal fetal ventricular rates (Fouron et al., 2003). The lack of variability in the heart rate provides a clue to the diagnosis. Atrial flutter can cooccur with reentrant SVT in 12%–33% of affected fetuses (Casey et al., 1997).

Sotalol has been shown to be effective in converting 50%–80% of fetuses with atrial flutter without mortality (Shah et al., 2012) and is considered first-line therapy. Digoxin is also recommended as a first-line therapy, and amiodarone may be considered; however, procainamide is contraindicated (Strasburger et al., 2004). Transesophageal pacing of synchronized cardioversion is recommended after delivery to restore sinus rhythm. Sinus node suppression may

rarely occur due to in utero therapy, and back-up external pacing should be available after cardioversion. Postnatal medical treatment should be reassessed given that atrial flutter may not recur (Donofrio et al., 2014).

Sustained Ventricular Tachycardia

Fetal VT is associated with AV block, cardiac tumors, myocarditis, and ion channelopathies. LQTS should be suspected when tachyarrhythmia and bradyarrhythmia coexist (Cuneo et al., 2003). Fetuses with LQTS can develop rapid TdP and monomorphic VT with subsequent development of ventricular dysfunction, AV valve insufficiency, and hydrops. Fetal magnetocardiography or ECG can confirm

the diagnosis by identifying a prolonged QTc interval (Strasburger and Wakai, 2010; Cuneo et al., 2013; Arya et al., 2015). Intrauterine IV magnesium is recommended as first-line therapy for VT greater than 200 bpm, and treatment should be limited to less than 48 hours. If maternal magnesium levels are less than 6 mEq/L and there are no signs of toxicity, redosing can be considered. IV lidocaine, oral propranolol, or mexiletine may also be considered in conjunction with magnesium, especially in the setting of hydrops. If LQTS can be excluded, then sotalol, flecainide, and amiodarone are alternative therapies and have been shown to be successful in terminating fetal VT. Dexamethasone and IV infusion of immunoglobulin (IVIG) have been used in the setting of antibody-mediated or myocarditis-associated VT (Donofrio et al., 2014).

Rare Tachycardias

Less common tachycardias such as AET and PJRT can be differentiated by the long RP interval (VA time) on fetal echocardiogram. The two can be differentiated by the gradual warm-up phase and variable AV nodal block at faster rates characteristic of AET and the sudden onset and consistent heart rate of PJRT. AET generally occurs at rates of 180–250 bpm and is most refractory to treatment both before and after birth (Strasburger, 2005). These fetal tachycardias occur in the late second or third trimester. Multifocal atrial tachycardia is rare (associated with Costello syndrome) and usually occurs in the last weeks of pregnancy (Lin et al., 2011). JET is commonly associated with SSA antibody exposure in the fetus and can be seen in the presence or absence of AV block. For AET and multifocal atrial tachycardia, treatment is recommended for average heart rates greater than 200 bpm with normal cardiac function or greater than 160 bpm with cardiac dysfunction (Donofrio et al., 2014). Digoxin is recommended as the first-line therapy, though flecainide and sotalol may be considered. Flecainide or sotalol are recommended for PJRT or rapid AET. Similar therapies can be used for the medical management of fetal JET, though amiodarone has also been used. Fetuses that develop JET in the setting of anti-SSA antibody exposure can be treated with dexamethasone as well. After delivery of a fetus with these rare tachycardias, continued medical treatment is usually required.

Sinus Tachycardia

Sinus tachycardia at rates of 180–190 bpm may mimic other pathologic tachycardias; however, ventricular dysfunction and hydrops are uncommon. Sinus tachycardia is associated with maternal infection, anemia, drug/medication use, hyperthyroidism, or trauma. Treatment of the underlying cause is recommended (Donofrio et al., 2014).

Arrhythmia Medications

Relatively high doses of antiarrhythmic agents must be administered during pregnancy because maternal circulating blood volume and renal clearance are both increased. In most cases, treatment should be initiated in the hospital with close observation of maternal and fetal well-being. A baseline maternal ECG and electrolytes, as well as a cardiology consultation, should be obtained before the initiation of medications to assess for maternal risk factors such as preexcitation or LQTS. Serial maternal ECG, electrolyte concentrations, and drug levels should be monitored throughout the duration of therapy. Oral medication administration is recommended, except for IV

magnesium and lidocaine, and for digoxin loading doses (Donofrio et al., 2014). Most arrhythmia medications demonstrate diminished transplacental transfer in the setting of hydrops, with the efficacy of digoxin decreasing to 25% (Srinivasan and Strasburger, 2008). However, flecainide and sotalol have been shown to be efficacious in the setting of hydrops (Donofrio et al., 2014). If the maternal PR, QRS, or QT intervals are noted to prolong during therapy with digoxin, flecainide, or sotalol, respectively, doses should be decreased and close observation is recommended. Serious maternal adverse reactions are rare and have resolved with discontinuation of therapy (Donofrio et al., 2014).

Fetal Bradycardia

Fetal bradycardia is defined as a persistent heart rate of less than 120 bpm. Causes include sinus bradycardia secondary to sinus node dysfunction, channelopathies, maternal exposures/conditions, or fetal central nervous system involvement and blocked atrial bigeminy, which is associated with a 10% risk for conversion to SVT. The most common cause of fetal bradycardia is congenital AV block, occurring in approximately 1:20,000 live births (Kertesz et al., 1997). Approximately 50% of fetal AV block is secondary to structural heart disease, 40% is due to immune-mediated mechanisms (Schmidt et al., 1991; Machado et al., 1988), and an additional 10% is idiopathic. Fetal congenital heart block at low heart rates is associated with significant morbidity and mortality, especially when associated with maternal autoimmune disorders. Management of fetal bradycardia is focused on frequent fetal echocardiographic evaluations to assess for the development of ventricular dysfunction, hydrops, or fetal heart rate less than 55 bpm. Treatment of nonimmune-mediated heart block is directed at augmenting fetal ventricular rates. For immune-mediated AV block, several therapies may be considered and are controversial (Jaeggi et al., 2004).

Benign Fetal Bradycardia

Maternal treatment with β -blockers, sedatives, and other medications has been associated with sinus node suppression. Fetuses with exposure to maternal anti-SSA/SSB antibodies or those with myocarditis may develop inflammation and fibrosis of the sinus node. Finally, fetuses with heterotaxy syndrome may develop bradycardia secondary to a low-atrial rhythm in left-atrial isomerism or dual sinoatrial nodes in right-atrial isomerism. In these conditions, fetal heart rates range between 90 bpm and 130 bpm. No treatment is recommended (Donofrio et al., 2014).

Blocked atrial bigeminy may result in fetal heart rates between 75 and 90 bpm with 2:1 AV conduction and can be mistaken for second-degree AV block. There is an increased risk of the development of fetal SVT, occurring in approximately 10% of fetuses with blocked atrial bigeminy (Donofrio et al., 2014). Fetal echocardiography may demonstrate normal AV conduction followed by an early atrial beat coupled to the preceding ventricular beat in which case the AV node is refractory. This results in failure of conduction to the ventricle (see Fig. 56.10). Management of blocked atrial bigeminy is the same as for isolated premature atrial contractions.

Ion Channelopathies

Congenital LQTS should be considered in the setting of persistent bradycardia in an otherwise asymptomatic fetus (Horigome et al., 2010). Measurement of the QTc can be performed by magnetocardiogram or

fetal ECG (Strasburger and Wakai, 2010; Cuneo et al., 2013; Arya et al., 2015). Fetal treatment is not recommended; however, the development of VT requires treatment as delineated in the Fetal Tachycardia section. Management involves close observation prenatally, correction of maternal electrolyte abnormalities, and avoidance of maternal exposure to QT-prolonging medications. Postnatal evaluation includes an ECG and continued observation and management of arrhythmias associated with LQTS (Donofrio et al., 2014).

Atrioventricular Block

Structural CHD accounts for 50% of fetal AV block. Fetuses with heterotaxy syndrome with left-atrial isomerism, congenitally corrected transposition, and AV canal defects are most at risk for the development of AV block. In a fetus the combination of congenital AV block, complex structural CHD, and hydrops fetalis is associated with a high rate of in utero demise (Anandakumar et al., 1996). AV block can be diagnosed by fetal echocardiogram by evaluating the atrial and ventricular rates and the AV relationships (Fig. 56.13A,B).

Maternal anti-SSA (Ro) and anti-SSB (La) antibodies are present in the majority of fetuses that develop isolated AV block. The presumed mechanism is that the fetal cardiac structures are a target for immune complex deposition, namely the AV node and the myocardium. Ro-52-specific antibody has shown a very close association with immune-mediated congenital AV block (Sonesson et al., 2004). The risk of heart block in mothers with anti-SSA/SSB antibodies is 2%–3%, with a recurrence rate after one affected child as high as 12%–17% (Buyon et al., 1998; Costedoat-Chalumeau et al., 2004). Autopsy specimens typically reveal progressive fibrosis of the AV nodal structures in affected fetuses. The process typically spares the His–Purkinje system so that the slower “escape rhythm” tends to be relatively reliable. Damage to the ventricular myocardium and the presence of endomyocardial fibroelastosis are also found in affected fetuses (Krishnan et al.,

2014). The risk of transfer of maternal antibodies to the fetus, and therefore the risk for development of AV block, is highest between 16 and 26 weeks’ gestation (Buyon et al., 1998). Close follow-up with fetal echocardiogram to evaluate fetal heart rate, PR interval for prolongation, and ventricular function is recommended every other week during this critical time period for all fetuses with exposure to anti-SSA/SSB antibodies. Fetal heart rate monitoring should be performed at standard intervals by the obstetrician.

Treatment of AV block depends on the cause, ventricular rate, and degree of heart failure. β -Sympathomimetics such as terbutaline, salbutamol, and isoprenaline are reasonable to use in fetuses with heart rates less than 55 bpm or with higher heart rates if there is significant CHD or signs of cardiac dysfunction or hydrops. Although terbutaline may increase the fetal heart rate, improvement in survival has not been demonstrated. Terbutaline is well tolerated; however, maternal heart rates of up of 100–120 bpm and benign ectopy have been reported (Cuneo et al., 2007). Immune-mediated AV block may benefit from dexamethasone (4–8 mg/day) or IVIG therapy. Dexamethasone has been shown to reduce inflammation, reverse or stabilize second-degree block, and improve hydrops or myocardial fibrosis and function (Krishnan et al., 2014). Risks associated with the use of dexamethasone include fetal growth restriction, oligohydramnios, effects on the central nervous system, and maternal diabetes. A trial of dexamethasone may be considered in fetuses with second-degree AV block or first-degree AV block with signs of cardiac inflammation (valve insufficiency, ventricular dysfunction, effusion) to prevent progression to complete AV block, though its usefulness has not been well established (Donofrio et al., 2014). The treatment of mothers with hydroxychloroquine before 10 weeks’ gestation has been associated with a reduced risk of anti-SSA/SSB antibody-mediated fetal cardiac disease and may be used in high-risk pregnancies (Izmirly et al., 2012).

• **Fig. 56.13** (A) Fetal mitral inflow and aortic outflow spectral Doppler and (B) M-mode of the fetal heart demonstrating 2:1 atrioventricular block with an atrial rate of 120 beats per minute and ventricular rate of 60 beats per minute. A, Sinus atrial activity; V, ventricular depolarization.

Long-Term Neurologic Outcomes in Children With Congenital Heart Disease

SHABNAM PEYVANDI AND PATRICK MCQUILLEN

KEY POINTS

- Congenital heart disease (CHD) is a common birth defect with improved survival of neonates with complex lesions requiring heart surgery.
- Neurodevelopmental (ND) abnormalities are common in school-age children and adolescents after neonatal heart surgery.
- Magnetic resonance imaging (MRI) studies have demonstrated evidence of brain injury and delayed brain development, even before having a corrective operation, in patients with hypoplastic left heart syndrome and transposition of the great arteries.
- Fetal MRI studies suggest this delayed development begins in the third trimester.
- Aberrant fetal physiology resulting in decreased oxygen and substrate supply to the brain may result in these imaging and ND abnormalities in addition to other perioperative risk factors.
- Children with complex CHD have a prevalence of pervasive but subtle cognitive problems termed *the neurodevelopmental signature of complex congenital heart disease*.

Severe congenital heart disease (CHD) requiring a corrective operation occurs in 6 to 8 per 1000 live births, with up to half of the cases requiring an operation in the neonatal period to survive (Hoffman and Kaplan, 2002). With improved surgical technique, mortality for CHD has steadily declined (Karamlou et al., 2010). In fact, the number of adults living with CHD has surpassed the number of children with CHD in the United States (Gilboa et al., 2016).

Given the changing epidemiology of CHD, considerable effort has been devoted to evaluating both neurodevelopmental (ND) outcomes and quality of life for patients with CHD. Evidence suggests that although children with CHD may no longer have overt signs of neurologic dysfunction, they may exhibit deficits in multiple domains including visual-spatial skills, memory, executive function, speech and language, and gross and fine motor function (Newburger et al., 2012; Sananes et al., 2012; von Rhein et al., 2012). Long-term follow-up data suggest that these deficits continue into adolescence and young adulthood with potential significant impact on societal contribution (Schaefer et al., 2013; Bellinger et al., 2009, 2011, 2015a,b).

A natural assumption has been that these adverse outcomes were directly related to brain injury sustained during neonatal cardiac surgical interventions. However, in the recent era it has become apparent that patient-specific risk factors play essential roles in determining the ultimate ND outcome and, furthermore, that the interplay between the brain and the circulation is complex, occurring at many levels throughout fetal and postnatal development. This chapter will review mechanisms influencing neurologic outcome in CHD including (1) the physiologic effects of congenital heart lesions on brain blood flow, (2) brain development in the context of CHD, (3) the timing, appearance, and mechanism of acquired brain injuries, and (4) current knowledge on ND outcomes in critical CHD in the short and long term.

Structural and Developmental Abnormalities of the Brain in Congenital Heart Disease

Human cardiac development is largely complete by gestational week 7 (Srivastava, 2006). In contrast, brain development extends over a much longer time period, with morphologic events (cell proliferation, migration, axon pathfinding, and target selection) occurring predominantly in the first two trimesters, followed by a prolonged period of refinement of circuits that begins in the third trimester and extends into infancy. This stage of brain development includes dramatic growth, myelination, and increasing neuronal electrical activity and depends upon receiving an adequate supply of nutrients and oxygen. Consequently, blood flow to the developing brain increases and is estimated to be a quarter of the combined ventricular output in the third trimester demonstrating the unique heart-brain interplay that is critical for normal brain development (Rudolph, 2011).

Fetal Circulation in Congenital Heart Disease: Effects on Cerebral Blood Flow

The fetal circulation is unique in a number of respects that can impact cerebral blood flow and development. In the normal fetus, cerebral blood flow is supplied by highly oxygenated blood from the ductus venosus preferentially streaming across the foramen ovale to

• **Fig. 57.1** Normal and Altered Fetal Circulation. (A) Normal fetal blood flow; (B) d-transposition of the great arteries (d-TGA); (C) hypoplastic left heart syndrome (HLHS) with aortic atresia. Deoxygenated blood (blue–purple) flows to the placenta through the umbilical artery. Blood with higher oxygen content (red) returns through the umbilical vein and ductus venosus to the inferior vena cava (IVC). The higher saturated blood from the IVC is preferentially directed toward the foramen ovale into the left ventricle, ascending aorta, and head and neck vessels in the normal fetus. Desaturated blood also returns to the right side of the heart and is directed to the descending aorta through the ductus arteriosus. In the fetus with d-TGA, the aorta arises from the right ventricle such that the brain receives less oxygenated blood, while the higher saturated blood is directed to the descending aorta through the ductus arteriosus. In HLHS, reduced or absent left-ventricular ejection results in elevated left-atrial pressure, limiting or reversing flow at the foramen ovale and resulting in complete mixing of desaturated and well-saturated blood in the right atrium and ventricle. Blood flow to the head and neck may occur in a retrograde fashion from the ductus arteriosus across the aortic isthmus. *d-TGA*, d-transposition of the great arteries; *DV*, ductus venosus; *HLHS*, hypoplastic left heart syndrome; *IVC*, inferior vena cava; *PV*, portal vein; *UA*, umbilical artery; *UV*, umbilical vein. (Reprinted with permission from McQuillen PS, Goff DA, Licht DJ. Effects of congenital heart disease on brain development. *Prog Pediatr Cardiol*. 2010;29(2):79-85.)

the left atrium and ventricle (Fig. 57.1). In contrast, in fetuses with transposition of the great arteries (TGA), the aorta and pulmonary artery are transposed and thus the higher oxygenated blood reaches the pulmonary vasculature as opposed to the cerebral vasculature. Similarly, in hypoplastic left heart syndrome (HLHS), inadequate left heart structures lead to reversal of blood flow in the foramen ovale with mixing of oxygenated and deoxygenated blood in the right ventricle and, in cases of aortic atresia, retrograde flow in the ascending aorta. The effects of these abnormal flow patterns on brain development are uncertain but may involve different mechanisms, despite the fact that both decrease the oxygen content of the blood delivered to the brain. Other mechanisms may be responsible such as inadequate substrate delivery (glucose) because of decreased perfusion pressure and flow to the brain (Rudolph, 2016). In d-transposition of the great arteries (dextroposition [d]-TGA), the pulsatility and perfusion pressure of the cerebral circulation are normal. However, in HLHS, the hypoplastic isthmus and aortic arch may function as resistors, potentially decreasing the pulsatility and perfusion pressure to the cerebral circulation. In contrast, in d-TGA, decreased pulsatility and perfusion to the brain can result

from preferential blood flow to the pulmonary vasculature because of a lower pulmonary vascular resistance than usual.

Cerebral Doppler ultrasound can assess fetal cerebral vascular resistance in the middle cerebral artery (MCA) and provide insight into fetal cerebral blood flow patterns. By calculating the MCA pulsatility index (PI, a measure of vascular resistance in the circulatory bed downstream from the point of Doppler sampling), studies have identified a pattern of “brain-sparing” in fetuses with intrauterine growth restriction and placental insufficiency as a mechanism of autoregulation of fetal cerebral blood flow (Wladimiroff et al., 1987; Mari and Deter, 1992). In normal pregnancies, the cerebral/umbilical PI ratio is more than 1.0, whereas in many growth-restricted fetuses the ratio is less than 1.0 and predicts adverse perinatal and neurologic outcomes (Rizzo et al., 1989; Gramellini et al., 1992). This autoregulatory mechanism is thus paradoxically a harbinger for poor outcome in the setting of fetal growth restriction.

There have been several studies examining in utero blood flow patterns in human fetuses with CHD. These have demonstrated lower MCA PI in fetuses who have lesions with the most intracardiac

• **Fig. 57.2** Middle cerebral artery Doppler patterns in a normal fetus and a fetus with hypoplastic left heart syndrome (HLHS). The pulsatility index (peak systolic velocity–end diastolic velocity/mean velocity) in the HLHS fetus is lower (*right panel*), suggesting decreased impedance in the cerebral vasculature. *PI*, Pulsatility index.

mixing, such as HLHS (Fig. 57.2). In fact, fetuses with HLHS have been shown to have the lowest cerebral/umbilical PI ratio among different types of CHD (Donofrio et al., 2003; Kaltman et al., 2005). This is likely secondary to the lower oxygen content of blood delivered to the brain as well as abnormalities in cerebral perfusion with a hypoplastic aortic isthmus.

Cerebral blood flow characteristics have been shown to predict ND outcomes in fetuses with CHD. In a retrospective multicenter study of infants with HLHS, a lower MCA PI in utero predicted a better ND outcome at 14 months of age as assessed by the Bayley Scales of Infant Development (BSID) II (Williams et al., 2013). These findings suggest that the autoregulatory response of cerebral vasodilation in the setting of HLHS may be sufficient and adaptive to a state of chronic hypoxemia, which is in contrast to what is seen in the context of fetal growth restriction. Further large prospective studies are needed to understand the predictive utility of cerebral blood flow patterns in fetuses with CHD.

Preoperative Evidence of Delayed Brain Development by Magnetic Resonance Imaging

Structural brain malformation in neonates with CHD has been identified, even in the absence of a defined genetic syndrome. Autopsy studies have revealed multiple congenital brain anomalies in neonates with HLHS including microcephaly, abnormal cortical mantle formation, and overt central nervous system malformations such as agenesis of the corpus callosum or holoprosencephaly (Glauser et al., 1990).

In addition to structural abnormalities, there is magnetic resonance imaging (MRI) evidence that brain development is delayed in CHD prior to corrective surgery. Quantitative MRI techniques such as diffusion tensor imaging (DTI) measure the direction and magnitude of water movement and thus microstructural brain development (Hüppi and Dubois, 2006). During normal brain development, the magnitude of water diffusion motion decreases (apparent diffusion coefficient [ADC]) and regional directionality increases in white matter (fractional anisotropy [FA]). Similarly, metabolic brain development can be measured with magnetic resonance spectroscopy (MRS) by measuring major metabolic compounds such as *N*-acetylaspartate (NAA), choline (Cho), creatine (Cr), and lactate. Using these techniques, researchers have discovered that newborns with CHD (d-TGA and single ventricle lesions) have findings suggesting an immature brain with abnormal DTI (4% higher ADC and 12% lower FA) and MRS (10% lower NAA/

Cho ratio). Comparing these findings with those obtained in premature newborns without CHD, full-term newborns with CHD appear approximately 1-month delayed (Miller et al., 2007). These observations have been replicated in studies assessing brain development by semiquantitative morphologic scoring, specifically the brain total maturation score (TMS). The TMS was found to be significantly lower in full-term newborns with d-TGA and HLHS compared with a normal cohort of newborns (Licht et al., 2009). Finally, morphometry studies have demonstrated lower total and regional brain volumes in newborns with CHD compared with controls (von Rhein et al., 2015). These findings help explain the abnormal somatic growth seen in the newborn with CHD. Specifically, those with d-TGA and HLHS have smaller head circumferences that are out of proportion to their weight (Rosenthal, 1996). These brain MRI findings in the neonate with CHD, seen before any corrective operations are performed, have led to the theory that abnormal brain development and susceptibility to acquired injury begin in utero.

Fetal Brain Magnetic Resonance Imaging Identifies Developmental Abnormalities in Congenital Heart Disease

Technical advances in fetal MRI have made it an important tool in the clinical evaluation of fetuses with suspected cerebral abnormalities. A study comparing brain volumes and MRS between normal fetuses and fetuses with CHD between 25 and 37 weeks' gestation showed definitive evidence for delayed fetal brain development (Limperopoulos et al., 2010). During the third trimester, a progressive impairment of brain volumes was observed, particularly in those fetuses with left-sided obstruction. Additionally, larger delays in the expected increase in NAA/Cho ratio and greater impairment of growth in brain volume were noted in fetuses with aortic atresia, who have no antegrade blood flow in the aortic arch. These observations support the concept that brain development is altered during fetal life because of impaired fetal cerebral blood flow, oxygen, and substrate delivery and that compensatory mechanisms (i.e., brain-sparing effect) may not be adequate.

Recently, novel fetal cardiac MRI techniques have been utilized to understand the heart–brain interplay in CHD. These techniques enable measurements of flow and oxygen saturation in fetal blood vessels. By combining fetal brain MRI and cardiovascular magnetic resonance, researchers found a correlation between fetal cerebral

oxygen consumption and brain size (estimated brain weight) among 30 fetuses with CHD in late gestation (Sun et al., 2015). There was a direct correlation between estimated brain weight and cerebral oxygen consumption. In addition, there was a modest association between cerebral oxygen delivery and brain size. The predictive value of these findings for postnatal outcomes such as brain injury and ND outcomes remains unknown. Further exploration to potentially identify targets and methods of intervention to modify ND outcome in CHD is warranted.

Trajectory of Brain Development in Congenital Heart Disease

Although much of the literature has been focused on the identification of abnormal brain development in the fetus and newborn with CHD, studies on older patients have emerged suggesting that these delays continue into adolescent years. In a study of single ventricle patients who had undergone a Fontan operation, the frequency of any structural abnormality on MRI was 11 times higher than in a normative cohort (Bellinger et al., 2015b). Similarly, in a brain MRI study of adolescents with d-TGA, FA was significantly reduced in several regions of the white matter compared with a normative cohort (Rivkin et al., 2013). Many have postulated that the trajectory of brain development over time may be dependent on the specific cardiac lesion and whether the surgical management is corrective (i.e., d-TGA) or largely palliative (i.e., HLHS). In particular, patients with aortic atresia have been found to have the least robust microstructural brain development (Sethi et al., 2013). Another study demonstrated, at 2.5 years of age, more cortical atrophy and lower brain volumes in those with HLHS compared with those with d-TGA, suggesting a lesion-specific influence on the long-term trajectory of brain development (Ibuki et al., 2012).

Acquired Brain Injury With Congenital Heart Disease: Characteristics and Risk Factors

Neonates with CHD are also at risk for newly acquired brain injury. Delayed brain development itself may be a risk factor for new brain injury, particularly preoperative injury.

Focal brain injury in the term newborn can be clearly and reliably detected with conventional MRI and with greater resolution than with either ultrasound or computed tomography. The most common brain injuries observed in newborns with CHD are focal white matter injury (WMI) and small focal strokes (less than one-third to two-thirds of the arterial distribution; Fig. 57.3). These injuries are largely clinically silent and can be overlooked with routine clinical screening cranial ultrasounds.

WMI has specific imaging characteristics defined by punctate periventricular lesions seen as hyperintensity on T1-weighted MRI. Identification of this pattern of injury was unexpected because it was thought to be restricted to premature newborns with brain injury (periventricular leukomalacia). Risk factors for brain injury are summarized below and in Table 57.1.

Risk Factors for Preoperative Brain Injury

Several large prospective studies have been performed using preoperative and postoperative brain MRI to determine the frequency of acquired brain injury and associated risk factors in newborns with CHD (Table 57.2). Preoperative brain injury in the form of WMI or stroke is present in 28%–39% of these newborns (Table 57.2) (Mahle et al., 2002; Licht et al., 2004; Miller et al., 2004; McQuillen et al., 2007; Mulkey et al., 2014). This was a surprising finding given the focus on operative factors causing ND abnormalities in these patients. Risk factors for preoperative brain injury include hypoxemia and time to surgery (Petit et al., 2009), preoperative base deficit, preoperative cardiac arrest, and the need for balloon atrial septostomy (McQuillen et al., 2006). Other patient-specific risk factors identified include male sex and the presence of aortic atresia (lack of antegrade flow in the aorta) in those with HLHS (Goff et al., 2014).

Risk Factors for Intraoperative Brain Injury

Proposed risk factors for intraoperative brain injury relate predominantly to the methods of cardiopulmonary bypass and/or hypothermic total circulatory arrest. The Boston Circulatory Arrest Trial compared two methods of vital organ support in infants

TABLE 57.1 Risk Factors for Brain Injury

| Preoperative | Intraoperative | Postoperative |
|--|---|--|
| Low arterial hemoglobin saturation | Prolonged total circulatory arrest (>40 minutes) | Low blood pressure |
| Length of time to surgery | Decreased cerebral oxygen saturation (NIRS) | Low arterial PaO ₂ |
| Catheter-based procedure (e.g., balloon atrial septostomy) | Cardiopulmonary bypass strategy (regional cerebral perfusion) | Prolonged cerebral regional oxygen saturation (NIRS <45% for >3 hours) |
| Preoperative base deficit | Air or particulate emboli | Morphologically immature brain (total maturation score) |
| Preoperative cardiac arrest | Inflammation | Single ventricle physiology |
| Morphologically immature brain (total maturation score) | | |
| Male sex | | |
| Aortic atresia | | |

NIRS, Near-infrared spectroscopy; PaO₂, partial pressure of oxygen.

• **Fig. 57.3** Magnetic Resonance Imaging Patterns of Brain Injury in Congenital Heart Disease. (A, B) Moderate white matter injury (WMI) in a newborn with hypoplastic left heart syndrome (HLHS) is seen on sagittal T1 images in the postoperative scan. WMIs appear as small focal areas of T1 hyperintensity (brightness). (C, D) Term newborn with HLHS imaged postoperatively at day 17 of life, after a modified Norwood procedure. A small middle cerebral artery distribution infarct is seen as cortical T2 hyperintensity (white arrows in [C]) and corresponding reduced diffusion (white arrows in [D]) in the right parietal-occipital lobe. (E, F) Term newborn with transposition of the great arteries imaged preoperatively after a balloon atrial septostomy. A single focus of T1 hyperintensity is seen in the peratrial white matter on the coronal sequence (E). This same focus has reduced water diffusivity on the average diffusivity map (F, dark spot). This spot is larger than the typical solitary white matter lesion and may represent a small embolic stroke.

TABLE 57.2 Magnetic Resonance Imaging Evidence of Preoperative Brain Injury in Newborns With Congenital Heart Disease

| Study | Sample | CHD | Findings | Risk Factors |
|-------------------------|-------------------------|-------|--|---|
| Mahle et al. 2002 | CHD = 24 | Mixed | PVL = 16% Infarct = 8% Elevated brain lactate = 53% | N/A |
| Miller et al. 2004 | CHD = 10 Control = 5 | TGA | Brain injury (stroke) = 40% Elevated brain lactate = 2.7 × higher than controls | N/A |
| Licht et al. 2004 | CHD = 25 | Mixed | PVL = 28% | <ul style="list-style-type: none"> Decreased cerebral blood flow Hypercarbia |
| McQuillen et al. 2007 | CHD = 62 | Mixed | WMI = 18% Stroke = 21% IVH = 8% | <ul style="list-style-type: none"> Low Apgar score at 5 min BAS |
| Petit et al. 2009 | CHD = 26 | TGA | PVL = 38% | <ul style="list-style-type: none"> Lower preoperative oxygen saturation Longer time to surgery |

BAS, Balloon atrial septostomy; CHD, congenital heart disease; HLHS, hypoplastic left side heart syndrome; IVH, intraventricular hemorrhage; N/A, not applicable; PVL, periventricular leukomalacia; TGA, transposition of the great arteries; WMI, white matter injury.

undergoing open heart surgery to repair d-TGA with an arterial switch operation (Newburger et al., 1993). This operation is “corrective” since normal cardiovascular physiology is reestablished with low mortality and excellent long-term cardiac functional outcomes. Although deep hypothermic circulatory arrest, which provides the surgeon with an empty and relaxed heart, clearly allowed intricate surgeries to be performed, there was concern at the time regarding late adverse neurologic outcomes and the “safe” duration of circulatory arrest was unknown. An alternative method (low-flow bypass) was felt to maintain some amount of brain oxygen delivery, while still allowing the surgeon a relatively bloodless field. This landmark study enrolled 171 infants into a single-center, randomized clinical trial comparing deep hypothermic total circulatory arrest with low-flow cardiopulmonary bypass. All of the early outcome variables pointed to a benefit from low-flow bypass compared with circulatory arrest. Specifically, the circulatory arrest group had more frequent postoperative seizures, higher serum levels of brain-specific enzymes (creatin kinase), worse 1-year motor outcome (BSID—Psychomotor Development Index [PDI]), and abnormalities on neurologic exam. In contrast, no differences were found in cognitive development (BSID—Mental Development Index [MDI]) or MRI at 1 year of age. Importantly, these differences between the groups disappeared when the patients were assessed at older ages, but both groups remained below population norms for performance on standardized tests (detailed later in this chapter) (Wypij et al., 2003). Other studies have identified circulatory arrest as a risk factor for new postoperative WMI identified on MRI (Beca et al., 2013).

Additional variables examined included hypothermic blood pH management (alpha stat versus pH stat), hemodilution/hematocrit (25% vs 35%), and maintenance of regional cerebral perfusion during aortic arch reconstruction (Jonas et al., 2003; Wypij et al., 2008). Very few of these studies have identified definitively improved neurologic outcomes. In fact, patients who underwent regional cerebral perfusion tended to have worse outcomes, and this technique was associated with new postoperative injury on brain MRI.

These results suggest that although risks remain during the intraoperative period, a major burden of risk for acquired injury occurs outside of the operative period. However, the possibility that unidentified intraoperative risk factors contribute to brain injury cannot be excluded. Analysis of combined cohorts of subjects requiring neonatal cardiac surgery over a 13-year period did not identify substantial improvement in early ND outcomes despite improvements in survival (Gaynor et al., 2015).

Risk Factors for Postoperative Brain Injury

Risk factors for postoperative brain injury include hypotension and hypoxemia related to low cardiac output syndrome, defined as a combination of clinical signs (tachycardia, oliguria, cold extremities, or cardiac arrest) and a greater than 30% difference in arterial–mixed venous oxygen saturation or lactic acidosis. Multiple studies have identified hypotension as a risk factor for new postoperative WMI, including low systolic blood pressure on admission, low mean blood pressure during postoperative day 1,

and low diastolic blood pressure during postoperative days 1 to 2 (Galli et al., 2004; McQuillen et al., 2007).

Studies utilizing cerebral near-infrared spectroscopy have also suggested that low regional cerebral oxygen saturation (<45%) for more than 3 hours was a risk factor for new ischemic injury (Hoffman et al., 2013). In general, patients with single ventricle lesions carry a higher risk of postoperative brain injury, which correlates with the higher postoperative hemodynamic instability, morbidity, and mortality.

Brain Immaturity as a Risk Factor for Brain Injury

The relationship between brain immaturity and brain injury has been explored in the literature although with variable results. Qualitative MRI (TMS) techniques have suggested an association between brain immaturity and the risk of preoperative and postoperative brain injury (Andropoulos et al., 2010). However, quantitative MRI techniques (DTI and MRS) have demonstrated an association between brain immaturity and the risk of preoperative brain injury but not postoperative brain injury (Dimitropoulos et al., 2013). Both studies suggest that brain immaturity may be a risk factor for brain injury with slightly different results. These differences likely relate to the method of measuring brain development. MRS and DTI exhibit changes with brain development and can be influenced by acquired brain injury based on severity, timing, and mechanism. Although overt brain injury has not been identified in the fetal period, indolent brain injury may be present influencing developmental changes and further injury in the preoperative and postoperative period.

Neurodevelopmental Outcomes

There is an increasing body of literature reporting short-term and long-term ND outcomes in patients with various types of CHD. Despite heterogeneity among these reports because of various methodologies for age at follow-up, assessment tools used, and type of cardiac lesion, these outcome data have provided us with useful knowledge on ND outcomes and provide the foundation for understanding imaging and clinical data in the fetal and neonatal period. Studies assessing the predictive value of fetal and neonatal imaging studies are lacking, and longitudinal studies are needed to assess the typical trajectory of brain growth and pattern of injury as these children grow older.

Immediate Neurologic Outcomes After Surgical Repair

Although the prevalence of overt neurologic dysfunction postoperatively has declined, a small percentage of infants continue to exhibit neurologic abnormalities including clinical seizures, hypotonia, and asymmetry of tone. Combining several reports, the prevalence of postoperative subclinical seizures appears to be 4%–11% and has been detected by continuous electroencephalogram monitoring in up to 20% of patients in the immediate postoperative period (Ehyai, et al., 1984; Newburger et al., 1993; Miller et al., 1995; Clancy et al., 2005; Gaynor et al., 2005; Gaynor et al., 2006). In a more recent study, a large percentage of young infants had evidence of ND abnormalities prior to surgery, suggesting that fetal and neonatal factors play a significant role in brain injury and development (Majnemer et al., 2009). In addition, there is a higher prevalence of feeding abnormalities (swallow or

suck dysfunction) in neonates undergoing cardiac surgery, which may be an early indicator of abnormal neurodevelopment later in life (Medoff-Cooper et al., 2015).

Short-Term and Long-Term Neurologic Outcomes After Surgical Repair

Although there have been several reports of ND outcomes in a mixture of CHD types, it is important to recognize that outcomes can vary significantly by cardiac lesion. Outcome studies have been carried out in two specific high-risk patient populations: those with d-TGA and those with defects requiring single ventricle palliation (i.e., HLHS).

In patients with d-TGA after an arterial switch operation, the Boston Circulatory Arrest Trial (described previously) has demonstrated that intelligence quotient (IQ) scores, although below the national average, fall within the normal range at 8 and 16 years of age (Bellinger et al., 2009; Bellinger et al., 2011). However, d-TGA patients at 16 years of age continue to exhibit deficits in academic achievement, memory, executive function, visual-spatial skills, attention, and social cognition. A high percentage of children were judged to have behavioral problems by parents and teachers; 37% required remedial education services and 10% had repeated a grade. Interestingly, in a multivariable regression model, socioeconomic status was a strong predictor of ND outcome in these patients at 16 years of age. These studies demonstrate that early ND testing may underestimate the ultimate burden of functional impairment in subjects with subtle but diffuse brain injuries.

Patients with single ventricle lesions, in particular HLHS, are at highest risk of ND abnormalities based on the underlying physiology, hemodynamics, and the complexity of surgical repair. These children must undergo a series of palliative surgical procedures typically culminating in a Fontan operation. Various studies have demonstrated that children with HLHS tend to have lower IQs (typically below the general population mean) and problems with visual–motor skills, expressive language, attention, and externalizing behavior. In the largest series reported to date, children with HLHS at 12 months of age had a median MDI of 90 (range 50–129) and a lower PDI of 73 (range 50–117) (Newburger et al., 2012). Risk factors for poor outcome were mainly patient specific and included genetic syndromes, earlier gestational age at delivery, and perioperative instability. Other studies have assessed the impact of growth and feeding issues on ND outcomes. Infants requiring device-assisted feeding and with lower weight, length, and head circumference at 3 months of age were at increased risk for ND delay at 6 and 12 months of age (Medoff-Cooper et al., 2015). Long-term studies have identified persistent ND abnormalities in adolescents with Fontan physiology including lower IQ and abnormal neuropsychological testing compared with a normative population (Bellinger et al., 2015b).

Genetic Susceptibility to Neurodevelopmental Abnormalities

An important point to consider is the impact of genetic comorbidities on ND outcome in the context of CHD. Approximately one-third of children with CHD have an underlying genetic disorder such as aneuploidy or deletion syndromes (i.e., 22q11.2 deletion syndrome). Studies have shown greater impairments in cognition, IQ, motor skills, hearing, and visual skills in those children, compared with children with CHD who do not have a genetic comorbidity (Pierpont et al., 2007; Marino et al., 2012). Several

studies have been performed in children with CHD who also have 22q11.2 deletion syndrome. This microdeletion encompasses three megabases of DNA, representing 30 to 40 genes, and the syndrome is highly heterogeneous with a variable phenotype. These patients have also been noted to have psychiatric disorders such as anxiety, attention deficit hyperactivity disorder, and psychosis. Interestingly, the presence of CHD does not change the prevalence of these psychiatric abnormalities (Yi et al., 2014).

Studies have also identified patient-specific genetic risk factors that can modify ND outcome. This has been described for alleles of apolipoprotein E (*APOE*) in which the ApoE ε4 allele is associated with adverse outcomes in many adult conditions (e.g., Alzheimer's disease, traumatic brain injury, stroke, and subarachnoid hemorrhage). This has been explored in infants with CHD and the ApoE ε2 allele is associated with worse outcome (Gaynor et al., 2014). Overall, it is likely that multiple genes and environmental factors influence ND outcome in these patients.

Neurodevelopmental Signature of Congenital Heart Disease

Although children with complex CHD have intelligence testing results in the range of the normal population, there is a prevalence of pervasive but subtle cognitive problems that some have termed a *neurodevelopmental signature of complex congenital heart disease*. These children show behavioral and attention problems that are often not detected on standardized testing but result in poor school performance. Among a large cohort of children who were followed prospectively after undergoing cardiac surgery as infants, abnormalities on neurologic exam at school entry were present in 28%, although less than 5% were severe. Most of the abnormalities involved fine motor coordination and tone. Cognitive difficulty and behavioral problems were identified in 30%. Certainly, survivors of CHD exhibit a “developmental profile” that changes in each stage of life and affects quality of life and the ability to perform everyday tasks (Majnemer et al., 2009). It is important to note that the American Heart Association released a statement paper recommending serial ND assessments for at-risk children with CHD (Marino et al., 2012). This includes neonates requiring open heart surgery (before 30 days of life) and other cyanotic heart lesions such as tetralogy of Fallot that may not require a neonatal operation. In addition, serial evaluation is recommended whenever CHD is seen in combination with prematurity (<37 weeks' gestation), developmental delay recognized in infancy, suspected genetic anomaly, history of extracorporeal life support, heart transplantation, the need for cardiopulmonary resuscitation, prolonged perioperative hospitalization, perioperative seizures, and abnormal neuroimaging findings.

Conclusions

Advances in prenatal diagnosis and care and cardiovascular surgical techniques have contributed to the overall increased survival of

neonates born with CHD. Given this improvement in survival, greater emphasis is now being directed toward improving ND outcomes. More specifically, understanding the predictive value of imaging studies both in the fetus and neonate provides an opportunity for potential intervention trials to improve outcomes among this patient population. In addition, as the prenatal detection of CHD increases, informing families about potential noncardiac adverse outcomes is critical to ensure recognition and timely intervention for ND abnormalities.

Central Nervous System Development

BOBBI FLEISS, HELEN STOLP, VALÉRIE MEZGER, AND PIERRE GRESENS

KEY POINTS

- The brain of the preterm and term newborn is actively developing, with several key steps occurring during the third trimester, such as the end of neuronal migration, programmed cell death, the generation of axons and dendrites, and the first wave of synaptogenesis.
- These processes are controlled by genetic programs but are also very sensitive to environmental factors.
- Epigenetic mechanisms appear to play a central role in these processes, with long-term and potentially transgenerational consequences.

Brain development results from the accomplishment of successive genetic programs during the different ontogenic stages. It starts with the individualization of the neural plate at the beginning of the third week postconception and is mostly complete by adolescence. However, some neuronal production persists lifelong: this late neurogenesis has been well described at the level of the olfactory bulbs and the dentate gyrus of the hippocampus; its importance to the associative neocortex remains to be shown.

The principal stages of brain development can be summarized as follows; induction of the neuroectoderm, formation of the neural tube followed by the telencephalon, neurogenesis (production of neuronal progenitors and then of mature neurons), neuronal migration, programmed neuronal death, generation of neurites (axons and dendrites), elimination of superfluous neurites, synaptogenesis, elimination and selective stabilization of synapses, angiogenesis, gliogenesis (production of astrocytes and oligodendrocytes), and myelination (Fig. 58.1). These different stages of the development and maturation of the brain are controlled by intrinsic factors (determined genetically) and modulated by extrinsic environmental factors. This modulation by environmental factors could bring epigenetic mechanisms into play.

The perturbation of the unfolding of any of these different stages of brain development leads to a deficit in brain growth and/or brain malformations. The functional consequences to the child depend on the developmental stage in question. This raises the notion of critical periods.

Neuronal Production and Migration

The expansion of the cortex occurs through two processes that take place in parallel: a lateral expansion process that allows the

surface of the cortex to grow and a radial expansion process that leads to an increase in its thickness. The total number of neurons in a mature human brain is estimated at between 3 and 100 billion. The cortex is initially generated from a monolayer of proliferative neuroepithelial cells lining the walls of the lateral ventricles—the ventricular zone (VZ). These cells are oriented radially. At approximately the seventh gestational week (GW) in humans, a second proliferative zone, the inner subventricular zone (SVZ), appears, derived from precursors in the VZ (Fietz and Huttner, 2011). The cells of the inner SVZ do not adopt a radial conformation. More recently, a third proliferative zone has been identified in the developing neocortex: the outer SVZ, which appears in humans at approximately GW 11. In humans, this zone displays prolonged proliferation whereas in rodents these cells only undergo a single division. This difference in the behavior of neuronal precursors could explain the impressive evolutionary expansion and folding observed in the surface of the neocortex.

These proliferative zones, situated on the dorsal side of the lateral ventricles, give rise to the excitatory (glutamatergic) neurons of the different cortical layers (the cortex in mammals consists of six layers), as well as a portion of inhibitory neurons (γ -aminobutyric acid [GABA]ergic interneurons). The other inhibitory neurons derive from another proliferative structure located on the lateral wall of the lateral ventricles, the ganglionic eminence, which is also the source of thalamic neurons. Migrating neurons can adopt a radial trajectory by migrating in contact with specialized glial cells, the radial glia, which serve to guide them (Gressens and Evvard, 1993; Haydar et al., 2003). In contrast, neurons originating in the medial eminence adopt an initially tangential trajectory, independent of radial glia, though there is some evidence of a final stage of radial migration.

After exiting the mitotic cycle, neurons migrate from the proliferative zones toward the future cortex (Rakic, 1971; Marin-Padilla, 1978; Rakic, 1978; Nieuwenhuys et al., 2007; Bystron et al. 2008; Fietz and Huttner, 2011). The first wave of migratory neurons forms the primitive cortical plate or preplate (Fig. 58.2). The second wave of migratory neurons then splits this primitive plate into two, at approximately GW 7, giving rise to a three-layered structure; layer I, which contains the Cajal–Retzius neurons, is located just below the meninges, layer VI, which contains neurons that have already completed their migration, and finally the subplate (SP)—a transient structure located below the future neocortex. Consecutive waves of migratory neurons subsequently cross the SP and the cortical layers already in place but stop below layer I, thus successively forming layers V, VI, III, and II along what is

known as an “inside-out” gradient (Angevine and Sidman, 1961) (see Fig. 58.2). Until recently, it was thought that the migration of neurons to the neocortex was complete by approximately GW 24 (Sidman and Rakic, 1973). However, recent studies suggest that GABAergic interneurons continue to be added to the neocortex practically until term (Xu et al., 2011). Premature birth could thus have an impact on this late migration (Leviton and Gressens, 2007). Interestingly, in a model of premature birth in baboons, when compared with fetuses of the same developmental age, a rarefaction of interneurons in the primary occipital cortex has been demonstrated (Verney et al., 2010).

Several molecules involved in controlling neuronal migration and their navigation to the appropriate destinations have been

• **Fig. 58.1** Schematic representation of the major ontogenic events taking place in the human neocortex.

identified. These molecules can be schematically divided into four categories (Gressens, 2006; Diaz and Gleeson, 2009).

1. Cytoskeletal molecules, which play an important role in the initiation and progression of neuronal movement (extension of the apical process and nucleokinesis). Molecules controlling initiation include Filamin-A (an actin-binding protein that is implicated in periventricular nodular heterotopias) and Arfgef2 (a molecule that plays a role in vesicular trafficking and is involved in periventricular nodular heterotopias associated with microcephaly). Among the molecules controlling progression are Doublecortin (a microtubule-associated protein [MAP] implicated in double cortex syndrome), Lis1 (a MAP implicated in Type 1 lissencephaly and Miller–Diecker syndrome), and α -1 Tubulin (involved in the formation of tubulin heterodimers).
2. Signaling molecules that play a role in lamination, such as Reelin (a glycoprotein implicated in a human disorder combining lissencephaly with cerebellar hypoplasia)
3. Molecules modulating glycosylation that provide a stop signal to migrating neurons, such as POMPT1 (protein *O*-mannosyltransferase, associated with Walker–Warburg syndrome), POMGnT1 (protein *O*-mannose β -1,2-N-acetylglucosaminyltransferase, implicated in muscle–eye–brain disease) and Fukutin (a glycosyltransferase implicated in Fukuyama congenital muscular dystrophy). These three human disorders display Type 2 lissencephaly.
4. In addition to these three principal groups of molecules, neuronal migration can be modulated by other factors such as certain neurotransmitters (glutamate and GABA), molecules derived

from peroxisomal metabolism, and certain environmental factors (ethanol and cocaine).

Programmed Neuronal Death

Depending on the brain region under consideration, 15%–50% of the neurons initially produced die through a physiologic process termed programmed cell death or apoptosis. Approximately 70% of the neurons that disappear seem to die between GWs 28 and 41 in humans (Bhutta et al., 2001).

Programmed cell death is a complex mechanism bringing into play a balance between cell death and survival-inducing signals, genetic programs involved in cell death or survival, and effectors of cell death and inhibitors of these effectors (Polleux et al., 2001). Under the influence of a combination of endogenous and exogenous factors, genetic programs are activated (as reflected in the term “programmed cell death”) and are capable of overcoming the natural defense mechanisms of the neuron. Once the cell is dead, it is rapidly phagocytosed by neighboring glial cells without inducing inflammatory phenomena or scar formation. This process is facilitated by changes in the composition of the apoptotic cell membrane, which occurs very early in the apoptotic process. Within the cell death process, the activation of caspases (proteolytic enzymes) in the form of a cascade is a key stage that culminates in DNA fragmentation and the death of the neuron.

Electrical activity appears to be a critical factor for neuronal survival. During the peak period of brain growth in rodents, the administration of substances that block electrical activity induces a serious aggravation of developmental neuronal death in various brain regions. These substances include *N*-methyl-D-aspartate receptor inhibitors (MK-801 or ketamine), GABA-A receptor agonists such as antiepileptics (phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, and valproic acid), and anesthetics (a combination of midazolam, nitric oxide, and isoflurane) (Turski and Ikonomidou, 2012).

Organization of the Central Nervous System

Subplate Neurons

SP neurons constitute a transient structure during brain development (Kostovic and Judas, 2002). They are generated at approximately GW 7, and the SP itself appears at approximately GW 10. This structure, located under the neocortical plate, reaches its maximum thickness between GWs 22 and 36.

SP neurons express various neurotransmitters, neuropeptides, and growth factors. They receive synapses and form connections with cortical and subcortical structures. These neurons play an important role during brain development; (1) they produce axons for the internal capsule, which act as guides for neurons from layers V and VI, (2) between GWs 25 and 32, they produce axons for the corpus callosum, and (3) they constitute a “waiting zone” for thalamocortical axons (with which they establish synapses) before the latter invade the neocortical plate to reach layer IV. This waiting area is necessary for the adequate targeting of thalamocortical afferents.

SP neurons may be destroyed in preterm newborns presenting with lesions of the periventricular white matter (Sarnat and Flores-Sarnat, 2001), findings which have been confirmed in animal models of periventricular white matter injury (McQuillen et al., 2003; Sfaello et al., 2005). This damage to the SP could participate in the thalamocortical connection anomalies recently demonstrated

by magnetic resonance imaging in preterm infants (Ball et al., 2013), as well as in the associated cognitive and/or motor disorders.

Axonal and Dendritic Growth

The final morphology of the neurons and the formation of connections between neurons depend on complex cellular interactions. Mature neurons develop dendrites and axons. In parallel, growing axons migrate toward their target neurons, which secrete chemoattractant or chemorepulsive factors and adhesion molecules, in order to form appropriate synapses. These chemoattractant or chemorepulsive axonal guidance molecules interact with receptors present on the growth cone and induce it to advance or to retract. The interaction between these different ligands and their receptors leads to modifications in calcium levels at the growth cone, which play a key role in growth cone motility and orientation. This ontogenic stage occurs largely, but not exclusively, during the second half of pregnancy and extends into the postnatal period.

The formation of corticospinal projections occurs at early stages from the SP and then from neurons that populate the deep cortical layers (V and VI). Corticothalamic projections also appear, from both the SP and the deep cortical layers. Corticocortical projections appear later.

It has been shown that a number of transcription factors (e.g., Ctip2, Satb2, Fezf2) regulate the commissural, corticothalamic, and corticospinal projections of the cortex. Even though genetic programs control the molecular mechanisms of axonal and dendritic growth and determine the initial pattern of these connections, experience and the environment then sculpt this global pattern to generate the final set of connections (through brain plasticity).

Synaptogenesis

The concept of synaptic stabilization (by the elimination of nonstabilized synapses) was first proposed by Changeux and Edelman (Changeux and Danchin, 1976). During brain development, there is a systematic overproduction of labile synapses in successive phases that leads to redundant connections in a fairly random manner. This stage is mainly controlled by genetic factors. Each wave of overproduction is followed by a period of stabilization of synapses that are of functional value and the elimination of redundant or useless ones. This period of stabilization and elimination is strongly influenced by environmental stimuli and experience. In this model, the moderate increase in the number of genes involved in synaptogenesis during the course of evolution has resulted in a richer substrate upon which the environment and experience act to generate a more complex network.

In the occipital neocortex of the monkey, five successive waves of synaptogenesis have been described (Bourgeois, 1997). Based on data obtained from the human occipital cortex (Lagercrantz and Ringstedt, 2001), the following chronology has been proposed for the human cortex: (1) a first phase starting at GW 6–8 and limited to the deep layers, such as the SP, (2) a second phase starting at GW 12–17, with relatively few synapses produced in the cortex, (3) a third phase starting at around the middle of pregnancy and finishing at around the 8th month after birth (this phase is characterized by a rate of production of new synapses estimated at around 40,000 per second in the monkey), (4) a fourth phase that extends up to puberty and is also characterized by a high rate of synapse formation, and (5) a final phase that extends up to adulthood but is somewhat masked by the significant

loss of synapses with age. Experimentally, the two first phases are not influenced by the deprivation of sensory stimuli. The third phase is partly dependent on sensory input whereas the fourth phase is strongly controlled by sensory stimuli and experience.

Glial Proliferation, Differentiation, and Myelination

Astrocytes

Neocortical astrocytes are of two origins (Gressens et al., 1992). At the end of neuronal migration, radial glial cells (which are both neural stem cells and play a role in guiding migrating neurons) are transformed into astrocytes, which then reside in the deep cortical layers and the white matter. In contrast, the astrocytes of the superficial cortical layers are primarily derived from glial precursors that multiply in the SVZ and then migrate into the cortex.

In the human neocortex, astrocytic proliferation probably begins at approximately GW 24, with a peak at approximately GW 26–28. The exact date at which the production of astrocytes ends is not known, but it could be supposed that the major part of astrocytic production is over by the end of a normal pregnancy. This peak in the production of astrocytes at a GW 26–28 could be of particular importance for preterm newborns. Indeed, astrocytes play several important roles, including axonal guidance, stimulation of neuronal growth, synapse formation, transfer of metabolites between blood vessels and neurons, establishment of the pattern of certain brain structures, production of extracellular matrix components, production of trophic factors, neuronal survival, myelination, and maintenance of the blood–brain barrier. For example, experimentally blocking astrocyte production temporarily in the neocortex of rodents induces an increase in programmed cell death in neurons and long-term changes in neocortical synaptic equipment (Zupan et al., 2000).

Oligodendrocytes and Myelination

Oligodendrocytes can be divided into four types depending on their degree of maturation.

1. Oligodendrocyte precursors that arise from the SVZ are bipolar and mitotically active; their differentiation into preoligodendrocytes occurs during their migration into the future/putative white matter.
2. Preoligodendrocytes are multipolar cells that retain their proliferative capacity. This second cell type is predominant in the periventricular white matter during the second half of pregnancy.
3. Immature oligodendrocytes are multipolar cells that appear during the third trimester and wrap axons in preparation for their myelination.
4. The last stage is their differentiation into myelinating and extremely multipolar mature oligodendrocytes.

The oligodendrocyte precursors and preoligodendrocytes, the predominant varieties in the brain of preterm newborns, are extremely vulnerable to oxidative stress, the excitotoxic cascade, and hypoxic–ischemic insults (Volpe, 2001). This death of preoligodendrocytes has been implicated in cystic periventricular leukomalacia. This type of severe lesion has progressively decreased in incidence, to be replaced by more diffuse lesions (Ferriero and Miller, 2010). Recent neuropathologic and experimental data suggest that, in this new type of white matter lesion in preterm infants,

the primary phenomenon is a blockade of oligodendrocyte maturation (Billiards, et al. 2008; Verney et al., 2010; Buser et al., 2012), in which the Wnt pathway plays a role (Fancy et al., 2011).

Myelination occurs during a prolonged period, persisting into childhood. The chronology and the degree of myelination vary according to the brain structure studied. There is no detectable myelination in the prosencephalon before the seventh month of pregnancy. Myelination in the telencephalon is most intense during the third trimester and postnatally and is mostly complete by the age of 2–3 years. The olfactory and auditory pathways and the sensorimotor cortex are the first to be myelinated, while projection and association pathways (in particular the prefrontal cortex) are the last (Girard et al., 2007).

Microglia

Microglia constitute 5%–15% of the total number of brain cells. Recent work in rodents suggests that cerebral microglia are derived from a pool of monocytic precursors that invade the amniotic sac early on and, from this pool, infiltrate the developing brain (Ginhoux et al., 2010). During the first trimester of pregnancy in humans, microglia that penetrate the brain have an amoeboid morphology. This morphology evolves progressively toward an intermediate and then a mature phenotype, with a small cell body and long processes. Around mid-pregnancy, microglial populations are principally detected in white matter fascicles such as the internal and external capsules, the corpus callosum, and axonal fascicle crossings (Monier et al., 2007). It is precisely in these regions of high microglial density that preterm infants develop the most white matter lesions (Verney et al., 2010). Experimental data support the hypothesis that microglia play an important role in the origin of these lesions (Tahraoui et al., 2001). Experimental studies show that during brain development, these cells participate to a significant extent in the physiologic phenomena of synaptic and neurite remodeling (Graeber, 2010). It is unknown how the fetal inflammatory response syndrome, which induces microglial activation, influences these developmental phenomena.

The Environment and Epigenetics

The different stages of brain development are finely controlled by diverse genetic programs. Nevertheless, experience, the environment, or stimulation can modulate, adapt, or refine the initial pattern to allow the brain to adjust to its environment. These adaptive processes are the expression of the great plasticity of the developing brain and allow the acquisition of new skills throughout childhood and adolescence. This is true even with regard to developmental stages that were initially thought to be almost completely controlled by genetic programming, such as the proliferation of neuronal precursors; experimental studies have shown that a maternal factor (vasoactive intestinal peptide) can change the proliferative capacity of these precursors by up to 20% (Passemard et al., 2011). However, the environment can also have deleterious effects on brain maturation. In particular, preterm newborns are exposed to numerous stimuli that exist only sparingly or not at all for a fetus of the same age, such as excessive or repeated sensory stimulation, painful stimuli, stress, several neuroactive drugs, as well as the brutal withdrawal of maternal and placental factors. Any environmental factor or drug that affects the brain is capable of altering a few or several stages of brain development.

The major mechanisms by which these environmental factors (positive or deleterious) act on brain maturation depend on the

epigenetic events that control the organization and compaction of the genome and thus the expression of genes. Chromosomes in eukaryotes result from a complex between DNA and a protein sheath called *chromatin*, whose basic unit is the nucleosome, around which the DNA is wrapped. Each nucleosome is composed of an octamer of histones (H2A, H2B, H3, and H4). The compaction of DNA—and thus the accessibility of genetic information to the transcriptional machinery—is regulated on the one hand by covalent modifications of the DNA and on the other by posttranslational modifications that decorate the N-terminal regions (tails) of histones (acetylation, phosphorylation, and methylation). The combination of these two types of events governs the opening or closing of chromatin (and thus the transcription or repression of the gene in question).

The methylation of DNA at CpG islands located in transcriptional regulatory regions of genes represses their transcription by blocking the binding of transcription factors to the DNA (Jones, 2012). DNA methyltransferases catalyze the methylation of DNA by using S-adenosyl-methionine (SAM) as a methyl group donor. In addition, the information deposited by the methylation of the DNA is “read” and “translated” by proteins that recognize methylated DNA: the methyl-CpG-binding proteins (MBPs). These MBPs recruit histone-deacetylases (HDACs), (and thus constitute the link between DNA methylation and the posttranslational modifications of histones), as well as other chromatin remodelers, and contribute to the establishment of transcriptionally inactive chromatin. The crucial role of histone acetylation in brain development is illustrated, for example, by the role of the histone-acetyltransferase CREB-binding protein (CBP), whose mutation in the heterozygous state is characteristic of Rubinstein–Taybi syndrome in humans and leads to anomalies of cortical gyration, a reduction of white matter, and regional hypoplasia in association with intellectual disability (Graff et al., 2011).

Remarkably, the level of DNA methylation is much higher in the brain than in other tissues and is essential for brain development in mouse models (Jones, 2012). DNA methylation especially affects neuronal differentiation and survival and the neurogenesis/gliogenesis “switch.” In humans, several syndromes with intellectual disability have a developmental origin linked to the DNA methylation pathway. This is the case with Rett syndrome, which is associated with mutations of the MBP MeCP2, and immunodeficiency–centromeric instability–facial dysmorphism syndrome, caused by mutations in *Dnmt3b* (Xu et al., 1999; Graff et al., 2011).

Finally, numerous imprinted genes (i.e., those expressed uniquely from the paternal or maternal allele), which are affected by epigenetic regulation, are expressed in the brain, and the deregulation of their expression is often associated with intellectual disability. This is the case, for example, with the neurodevelopmental syndromes, Prader–Willi and Angelman syndromes (Chamberlain and Lalonde, 2010).

Interestingly, fetal stress modifies the pattern of DNA methylation of key genes involved in neurodevelopment and the integrity of

the adult brain (such as *BDNF*, *Reelin*, and *GAD67*) (Graff et al., 2011). Thus women suffering from depression or anxiety-related disorders during the third trimester of pregnancy give birth to newborns in whom the promoter region of the glucocorticoid receptor gene is hypermethylated. Additionally, neuronal plasticity, learning, and memory rely on the establishment of epigenetic events and neuronal activity in particular modifies patterns of DNA methylation (Guo et al., 2011).

In summary, one could thus speak of “neuro-epigenetics” and all that this entails in terms of future therapeutic possibilities, since an in-depth knowledge of epigenetic events and their reversibility opens the door to the search for compounds that could remodel the epigenome of the brain and reprogram neural cells. In this context, it is of interest to note that diets poor in methionine (the precursor of SAM) and treatment with HDAC inhibitors (such as valproic acid) have been widely prescribed for psychiatric disorders such as schizophrenia or bipolar disorder, as well as in diverse forms of addiction (Graff et al., 2011).

Congenital Malformations of the Central Nervous System

SARAH BAUER HUANG AND DAN DOHERTY

KEY POINTS

- Brain malformations are a substantial source of morbidity and death in neonates.
- Advances in imaging and genetics now allow more specific diagnoses.
- Early and specific diagnosis allow more precise prognostic and recurrence information to be obtained and improved monitoring for complications and can guide treatment
- Early diagnosis and management of patients with brain malformations require multidisciplinary team management.

This chapter will focus on congenital malformations of the central nervous system (CNS), including developmental disorders of the spinal cord and forebrain, midbrain, and hindbrain. When possible, examples of imaging in the fetal or neonatal period will be used to highlight these anomalies. Within each section we will review relevant embryology, discuss the known genetic or environmental risk factors, and briefly discuss management, if applicable. Categorization of brain malformations has evolved over time. Initial categories were based solely on clinical and pathologic features. Brain imaging has added greatly to our ability to distinguish different malformations, followed by remarkable advances in genetics and the elucidation of molecular mechanisms. Classifications will continue to evolve with further developments in all of these areas.

Prosencephalic Cleavage and Related Events

Normal Prosencephalic Development

The prosencephalon refers to the future forebrain, which includes the telencephalon and the diencephalon; these structures give rise to the cerebral hemispheres and the thalamus/hypothalamus. The prosencephalon develops after closure of the anterior neuropore, through processes that induce the bifurcation of the rostral extent of the fluid-filled neural tube (Fig. 59.1) to form the right and left forebrain structures (Rubenstein and Beachy, 1998). During the fifth and sixth weeks of development, the structure of the forebrain is defined by cleavage along three major planes. As the

anterior neuropore is closing, the first major event is formation of the optic vesicles and nasal placodes, separated along the *horizontal* plane. When the embryo has reached a length of about 5 mm, both neuropores have closed, isolating the developing ventricular system from the amniotic fluid. The retinal and lens placodes also develop at this time. In the hindbrain the cerebellum begins to form, along with somatic and visceral efferent nuclei, the common afferent tract, and the ganglia for most of the cranial nerves. At about day 32 of gestation, when the embryo is 5 to 7 mm long, the forebrain divides in the *sagittal* plane to give rise to the paired structures. Specific areas, including the hypothalamic, amygdala, hippocampal, and olfactory regions, can be defined at this time. The third major event in forebrain development occurs shortly thereafter when the forebrain divides in the *coronal* plane. This event separates the telencephalon from the diencephalon, defining the epithalamus, subthalamus, and hypothalamus. During the remainder of the second and third months of gestation, multiple midline structures form, including the corpus callosum, anterior and hippocampal commissures, optic nerves, optic chiasm, and hypothalamus.

Disorders of Structures Derived From the Prosencephalon

Disorders of development of the prosencephalon include the severe malformations: atelencephaly, aprosencephaly, and holoprosencephaly (HPE). Milder defects include agenesis of the corpus callosum (ACC), septo-optic dysplasia (SOD), and isolated absent cavum septi pellucidi (CSP).

Aprosencephaly and Atelencephaly

Aprosencephaly and atelencephaly are two rare and very severe cerebral malformations. In aprosencephaly, neither prosencephalic nor diencephalic structures develop. In atelencephaly, there remains a rudimentary prosencephalon. Craniofacial abnormalities are secondary to deformation rather than malformation (Siebert et al., 1987). These disorders may result from possible autosomal recessive inheritance versus an abnormality of chromosome 13 (Ippel et al., 1998). Aprosencephaly/atelencephaly has also been reported in a family with mutations in the *SIX* gene, which has also been

GASTRULATION

A

NEURULATION

B

• **Fig. 59.1** Formation of the Neural Tube. (A) During gastrulation, at the neural plate stage, dorsoventral polarity and early anteroposterior regionalization are defined by a process of vertical induction by fibroblast growth factor 8 and other factors (*long gray arrows*) derived from mesendoderm (notochord and prechordal plate). Planar induction occurs via bone morphogenetic proteins (BMPs) and BMP inhibitors that are derived from lateral ectoderm (*short light gray arrows*) and the Hensen node (*short dark gray arrows*) respectively. (B) The process of neurulation proceeds with the approximation of the neural folds toward the dorsal midline. Before closure of the neural tube, neural crest cells delaminate and migrate from the neural folds. Dorsalizing factors (BMPs; *dark gray arrow*) derived from the dorsal midline roof plate (RP) and ventralizing factors (sonic hedgehog [SHH]; *light gray arrow*) from the floor plate (FP) establish dorsal-ventral gradients of these key signaling molecules that induce formation of the alar plate (AP) and the basal plate (BP) from the lateral wall of the neural tube. (Adapted from Vieira C, Pombero A, García-López R, Gimeno L, Echevarría D, Martínez S. Molecular mechanisms controlling brain development: an overview of neuroepithelial secondary organizers. *Int J Dev Biol.* 2010;54:7–20, courtesy of Dr. Salvador Martínez, Institute of Neuroscience, Universidad Miguel Hernández, San Juan de Alicante, Spain.)

associated with HPE (Pasquier et al., 2005). Typically, these are diagnosed prenatally by ultrasound and fetal magnetic resonance imaging (MRI) (Nagaraj et al., 2016). Although considered “lethal” malformations, it is important for the neonatologist to be prepared for infants with severe malformations to live longer than expected and even go home from the hospital.

Holoprosencephaly

HPE represents a spectrum of defects in forebrain development and is the most common brain malformation (Norman et al., 1995; Barr and Cohen, 1999), although most affected fetuses are miscarried early in gestation. HPE represents a variable degree of

• **Fig. 59.2** The Spectrum of Holoprosencephaly as Demonstrated by Magnetic Resonance Imaging. (A, B) Magnetic resonance imaging (MRI) of the brain in a patient with alobar holoprosencephaly. The T1-weighted axial image (A) reveals lack of separation of the two hemispheres and deep gray nuclei. A large dorsal cyst (dc) is observed posteriorly. The T1-weighted sagittal image (B) reveals a midline monoventricle (mv) that communicates posteriorly with the dorsal cyst (dc). (C, D) MRI of a patient with semilobar holoprosencephaly. The T2-weighted axial image (C) indicates separation of the hemispheres posteriorly but not anteriorly. Anterior horns of the lateral ventricles are absent, whereas the posterior horns are well formed and separated. Note the formation of a posterior dorsal cyst (dc). There is also an incomplete separation of the basal ganglia. The T2-weighted coronal image (D) reveals a lack of interhemispheric fissure and a monoventricle (mv). (E, F) MRI of the brain in a patient with lobar holoprosencephaly. The T1-weighted axial image (E) reveals that the two hemispheres are fairly well separated as manifested by the presence of an interhemispheric fissure both anteriorly and posteriorly. Note that the frontal horns of the lateral ventricles are only rudimentary (black arrowheads). The T1-weighted coronal image (F) documents incomplete separation of the inferior frontal lobes near the midline. (G, H) MRI of the brain in a patient with the middle interhemispheric variant of holoprosencephaly. The T1-weighted axial (G) and coronal (H) images demonstrate the continuity of gray matter in the posterior frontal lobes across the midline (arrows). (From Hahn JS, Plawner LL. Evaluation and management of children with holoprosencephaly, *Pediatr Neurol.* 2004;31:79–88.)

incomplete separation of the prosencephalon along one or more of its three major planes (discussed earlier). The DeMyer classification scheme includes “alobar,” “semilobar,” and “lobar” divisions (DeMyer et al., 1964) and a milder middle interhemispheric variant subtype, also referred to as *syntelencephaly*; however, HPE can be difficult to classify in a given patient. In *alobar* HPE (Fig. 59.2), a single anterior ventricle is contained within a holosphere with complete lack of separation of the prosencephalon. Alobar defects may be classified by fetal imaging findings. Depending on the

severity of the defect, other midline structures such as olfactory bulbs/tracts, the corpus callosum, anterior commissure, and the optic nerves may be affected. In addition, midline deep structures such as the basal ganglia, hypothalamus, and thalamic structures are fused, and vascular malformations may also be present (Winter et al., 2015). The milder *semilobar* and *lobar* forms still have distinct hemispheres and the presence of a portion of the posterior corpus callosum. Semilobar forms are suggested if the frontal lobes are more than 50% fused, and the thalami and hypothalamus may also be fused. Lobar HPE is associated with the fissure along almost the entire midline and separation or near separation of the thalami and absence of the CSP. A middle hemispheric variant has been described in which the posterior frontal and parietal lobes fail to separate, with absence of the body of the corpus callosum (Barkovich and Quint, 1993; Lewis et al., 2002). Typically, patients with the middle interhemispheric variant are not identified in the neonatal period unless the variant was diagnosed prenatally. Finally, a septo-preoptic type has been suggested, where the nonseparation is restricted to the septal and preoptic areas (reviewed in Solomon et al., 2013).

Diagnosis

With the advent of prenatal ultrasonography, patients with HPE are usually identified before birth. Alobar HPE may be identified as early as 10 weeks’ gestation and can be reliably identified by 14 weeks. False-positive findings by ultrasonography are common (Kaliaperumal et al., 2016), so fetal MRI can be very useful for clarifying the diagnosis and severity of the malformation, particularly if pregnancy termination is being considered. Subtle findings such as absence of CSP may suggest the milder forms of HPE, although absent CSP can be isolated or associated with ACC (Winter et al., 2015). Given the high rate of chromosome abnormalities, amniocentesis for chromosome array and possibly DNA sequencing is indicated (Solomon et al., 2013).

Clinical Features

Up to 80% of children with HPE have a craniofacial anomaly (reviewed in Solomon et al., 2013). The findings may range from cyclopia (a single central eye) with a nose-like structure (proboscis) above the eye, to cebocephaly (a flattened single nostril situated centrally between the eyes), to median cleft lip. Mild cases may have a single central incisor or hypotelorism. The concept of “the face predicts the brain,” refers to the fact that more severe facial malformations are often associated with more severe brain malformations; for example, patients with alobar HPE can have normal facies, while those with lobar or semilobar HPE can have severe facial malformations (DeMyer et al., 1964; Cohen, 1989; Plawner et al., 2002).

Newborns with HPE present with low tone and microcephaly, unless hydrocephalus occurs (Hahn and Plawner, 2004) due to the blockage of cerebrospinal fluid (CSF) flow through the fused thalami and is often associated with a large dorsal cyst (Simon et al., 2001). Ventriculoperitoneal shunts can relieve symptoms of increased intracranial pressure (Levey et al., 2010). Over time, patients may develop spasticity and dystonia. Oromotor dysfunction is frequent, and many children with HPE require tube feedings.

As with other midline brain defects, endocrinologic abnormalities are very common. Diabetes insipidus occurs in up to 70% of patients, with hypothyroidism, hypoadrenocorticism, and growth hormone deficiency being less common (Hahn et al., 2005). These endocrine abnormalities can develop over time, requiring periodic monitoring. Hypothalamic dysfunction may also cause irregularities of sleep, temperature regulation, appetite, and thirst.

Only about 40% of children have epilepsy, but one-third of these will have intractable epilepsy (Plawner et al., 2002; Levey et al., 2010). Seizures may also be provoked by endocrinologic abnormalities such as hypernatremia or hypoglycemia. Given the range of possible medical issues, a multidisciplinary approach to the care of these children is necessary, as is continued surveillance for potential complications such as hydrocephalus, seizures, and pituitary insufficiency.

Prognosis is related to the severity of the defect, involvement of other organ systems, and the genetic cause (Winter et al., 2015). Fetal or neonatal death is typical for most individuals with chromosome abnormalities (Croen et al., 1996). In contrast, more than 50% of cytogenetically normal patients with all types of HPE are alive at 12 months (Olsen et al., 1997; Barr and Cohen, 1999). Survival into late adolescence and adulthood has been reported (Plawner et al., 2002; Levey et al., 2010).

Epidemiology and Etiology

The live birth prevalence of HPE is 1 in 10,000 to 1 in 20,000 (Croen et al., 1996; Rasmussen et al., 1996; Croen et al., 2000; Orioli and Castilla, 2010). The prevalence is higher in miscarried embryos and fetuses, representing as many as 50 per 10,000 pregnancies.

The cause of HPE is multifactorial, with both genetic and environmental factors appearing to contribute to the variable spectrum of presentations (Norman et al., 1995; Golden, 1998; Muenke and Beachy, 2000). Up to 45% of HPE is caused by chromosomal abnormalities detectable by standard karyotyping (Winter et al., 2015). The most common chromosome abnormalities are trisomies 13 and 18 (Solomon et al., 2010c). Chromosome microarrays can identify smaller copy number variants in 10%–20% of individuals with HPE with normal karyotypes (Bendavid et al.,

2009). Mutations in at least 14 genes have been associated with HPE, accounting for up to 25% of syndromic forms (e.g., Smith–Lemli–Opitz, Meckel, Rubenstein–Taybi, Kallman, and Pallister–Hall syndromes) (Muenke and Beachy, 2000). Six genes have been well established to cause nonsyndromic HPE: *SHH*, *ZIC2*, *SIX3*, *TGIF*, *GLI2*, and *PTCH1*. *SHH* accounts for up to 40% of familial cases of HPE (Roessler et al., 1996; Nanni et al., 1999).

Genotype–Phenotype Variability

HPE is characterized by extreme intrafamilial variability. Asymptomatic or mildly affected family members may carry a deletion for a gene associated with HPE, whereas in a subsequent generation, offspring with the same deletion may be severely affected. Incomplete penetrance can result in “microforms,” including hypotelorism, midface hypoplasia, or a single central incisor (reviewed in Petryk et al., 2015). One explanation for these observations comes from studies suggesting that the mode of inheritance for HPE may be multigenic (Ming and Muenke, 2002). The severity of expression of the HPE phenotype throughout a given family may be influenced by the additive contributions from multiple genetic factors and environmental or teratogenic effects.

Some genotype–phenotype correlations have emerged. Patients with *ZIC2* mutations can have a characteristic facial appearance (bitemporal narrowing, upslanting palpebral fissures, large ears, and a short nose with anteverted nares). *ZIC2* mutations also appear to be the most common de novo mutation and have a high penetrance (Solomon, Gropman, and Muenke, 2013).

Environmental Factors

Environmental factors (e.g., ethanol, vitamin A toxicity) can produce cyclopia during the early phase of gastrulation. Maternal diabetes mellitus increases the risk of HPE to approximately 1%–2% of all pregnancies. Cholesterol-lowering agents have been associated with HPE (Edison and Muenke, 2003), presumably because of effects on *SHH* signaling. Smith–Lemli–Opitz syndrome is caused by a defect in the terminal step of cholesterol biosynthesis, and HPE manifests itself in approximately 5% of affected individuals. Additionally, ingested plant alkaloids have caused epidemics of cyclopia in sheep by processes that inhibit cholesterol biosynthesis. Other environmental associations (cytomegalovirus [CMV] infection, medications, assisted reproductive technologies) have been suggested by case reports or animal studies (reviewed in Petryk et al., 2015).

Agensis of the Corpus Callosum

The corpus callosum consists of approximately 190 million axons and is formed by a complex, multistep process that involves cellular proliferation and migration, axonal growth, and midline patterning (Raybaud, 2010). Formation of the corpus callosum is mediated by many genes, and completion takes at least 11 weeks (O’Driscoll et al., 2010). Development continues through adolescence as these connections are refined (Palmer and Mowat, 2014). Genetic and environmental factors affect callosal formation and can result in complete ACC or hypoplasia. Genetic syndromes associated with ACC also have additional malformations such as cerebellar hypoplasia, microcephaly, and polymicrogyria (PMG) (O’Driscoll et al., 2010).

ACC results in abnormal gyration of the medial portion of each hemisphere, eversion of the cingulate gyri, and sulcation perpendicular to the long axis of the hemisphere (Barkovich and Norman, 1988). The external angles of the lateral ventricle are

oriented parallel and upward, and the fornices are widely separated. If present, a useful distinguishing feature is Probst bundles (Fig. 59.3), which are fiber bundles that run parallel to the ventricle in an anterior-to-posterior direction. ACC can be partial, more often involving loss of posterior segments (Schaefer et al., 1991; Roessmann, 1995). In addition to ACC, additional findings can be present, such as cysts or lipomas (see Fig. 59.3). CNS malformations seen in association with ACC can include heterotopia, sulcation, commissural and white matter abnormalities, and malformations of the posterior fossa (Hetts et al., 2006).

Epidemiology and Etiology

The prevalence of ACC ranges from 0.5 in 10,000 in the general population to 600 in 10,000 in children with neurodevelopmental disability (reviewed in Palmer and Mowat, 2014). ACC can also be associated with prenatal infections, vascular, and teratogen effects (Palmer and Mowat, 2014). However, infection usually causes thinning rather than agenesis and is a rare cause of isolated ACC. Ethanol exposure has the strongest association with ACC, which was reported in 7% of children with fetal alcohol syndrome in one series (Roebuck et al., 1998).

ACC is a feature of hundreds of different disorders, and all modes of inheritance have been observed. Glass et al. (2008) found that callosal anomalies were associated with a chromosomal abnormality 17% of the time, commonly aneuploidy (chromosomes 13, 18, and 21). ACC may be associated with either inherited or de novo copy number variants, some overlapping with those found in patients with autism (Sajan et al., 2013). ACC is also a primary feature of several important disorders, such as Mowat–Wilson, Aicardi, acrocallosal syndromes, *LICAM*-related spastic paraplegia, and X-linked lissencephaly with ACC and ambiguous genitalia. Given the number of genetic syndromes associated with ACC, Palmer et al. (2014) have suggested a subdivision of groups based on the associated conditions (craniofacial, metabolic, ocular, ciliopathies), which aids in the diagnostic evaluation of these patients.

Prenatally, fetal MRI at 20 to 22 weeks' gestation maximizes the identification of additional cerebral findings when pregnancy decision making is still an option. Earlier MRI scans yield more false-negative results and miss structural changes. Additional diagnostic options include genetic (chromosomal microarray, cell-free fetal DNA) and infectious (serologic tests, polymerase chain reaction testing on amniotic fluid) disease testing. Given the challenges with accurate prenatal diagnosis, newborns should be evaluated by brain MRI shortly after birth (when sedation is not required) and by subspecialty consultations (neurology, ophthalmology, genetics, developmental pediatrics, audiology). Laboratory testing (chromosome microarray, DNA sequencing, metabolic testing) should be considered, depending on the examination and MRI findings. Surveillance for neurodevelopmental issues, visual impairment, and pituitary insufficiency is recommended (Palmer and Mowat, 2014).

Prognosis

The outcomes of ACC are variable. A systematic literature review revealed that up to 75% of patients with MRI-confirmed isolated ACC were developing typically at early school age, while 11% had severe disability (Sotiriadis and Makrydimas, 2012). Microcephaly, epilepsy, cerebral palsy, and cerebral dysgenesis are associated with higher risk of abnormal neurodevelopmental outcome. Neuropsychological studies have shown specific impairment in abstract reasoning, problem solving, and category fluency (Fischer et al.,

1992; David et al., 1993). Difficulty with higher-level language such as comprehension of syntax and linguistic pragmatics has also been demonstrated (Banich and Brown, 2000). These findings underscore the need for continued evaluation for learning and language difficulties in these patients.

Septo-Optic Dysplasia

Classic SOD is the triad of the absence of the septum pellucidum, optic nerve hypoplasia, and pituitary dysfunction. The diagnosis of SOD is made when two or more features of the triad are present (Webb and Dattani, 2010); 30% of patients have all three features (Morishima and Aranoff, 1986). SOD is a clinically and etiologically very diverse group of disorders and overlaps with isolated optic nerve hypoplasia (Garcia-Filion and Borchert, 2013), and this diversity makes it difficult to provide counseling about prognosis and associated medical issues.

Diagnosis and Prognosis

Prenatally, SOD may be suspected in fetuses with absent CSP or ACC, although most fetuses with isolated absent CSP do not have SOD, posing a challenge for counseling. Postnatally, SOD may be suspected in a patient with growth failure, visual abnormalities, or genital abnormalities. Early diagnosis is important to reduce the risk of adrenal crisis and hypoglycemia and requires brain MRI, ophthalmologic evaluation, and laboratory testing for pituitary insufficiency.

Children with SOD may be blind or have visual impairment, presenting with roving gaze, nystagmus, or strabismus. Neurodevelopmental prognosis is controversial and may be correlated with the presence of other brain abnormalities. In early studies, cerebral palsy was found in 57% of children with SOD, intellectual disability was found in 71%, epilepsy was found in 37%, and behavioral problems were found in 20% (Acers, 1981; Margalith et al., 1984). A later neurodevelopmental study of seven children with unilateral or bilateral optic nerve hypoplasia with the absence of CSP found normal cognitive development, intact neurologic status, normal language development, and age-appropriate behavior in six of the seven children (Williams et al., 1993). Conversely, a descriptive series of three children with SOD plus cortical dysplasia showed that all three had abnormal development and neurologic examination findings (Miller et al., 2000). Developmental, neurology, endocrinology, and ophthalmology specialists should follow up these children. Hypopituitarism is seen in up to 80% of patients, with growth hormone deficiency being most common. Lifelong monitoring is needed, because of evolution of pituitary insufficiency over time (Webb and Dattani, 2010).

Epidemiology and Etiology

The prevalence of SOD is 1 in 10,000 births, with increased risk in younger mothers (Murray et al., 2005). Mutations in several genes have been associated with SOD (e.g., *HESX1*, *SOX2*, *SOX1*, *OTX2*) (Webb and Dattani, 2010; McCabe et al., 2011); however, a genetic origin is not identified in most patients, suggesting environmental or complex genetic causes. The disease is sporadic in most patients, and SOD can exhibit dominant and recessive modes of inheritance. Some instances of SOD have been associated with prenatal drug and alcohol exposure or a vascular pathogenesis (Lippe et al., 1979; Lubinsky, 1997; Stevens and Dobyns, 2004); however, these associations remain unproven. The recurrence risk is less than 1% in the absence of consanguinity.

• **Fig. 59.3** Findings Associated With Agenesis of the Corpus Callosum as Demonstrated by Magnetic Resonance Imaging. (A) Coronal fetal magnetic resonance imaging (MRI) demonstrating the presence of the corpus callosum. Note that the medial cortex curls toward the midline. (B) Coronal fetal MRI demonstrating agenesis of the corpus callosum (ACC). Note that the medial cortex curls away from the midline. (C) Postnatal axial T2-weighted image of ACC demonstrating colpocephaly and classic Probst bundles (arrows). (D) T1-weighted sagittal section demonstrating near complete ACC (rostrum remains). (E) Postnatal axial T2-weighted image demonstrating a multiloculated cystic structures (arrow) that can be seen with ACC. (F) T1-weighted sagittal image demonstrating a lipoma (bright white area) that can be seen with ACC.

• **Fig. 59.4** Fetal and Postnatal Magnetic Resonance Imaging With Absent Cavum Septi Pellucidum. (A) Fetal magnetic resonance imaging (MRI) demonstrating expected cavum septi pellucidum (CSP) at 21 weeks' gestation (arrow) (B-D) MRI demonstrating absent CSP (arrow) at 20 weeks' gestation (B), 34 weeks' gestation (C), and birth (D). The fetus in (B) also has mild ventriculomegaly.

Absent Cavum Septi Pellucidum

CSP is a common finding on ultrasonography and MRI of fetuses and premature infants. This normal finding represents a fluid-filled space between the lamellae of the septi pellucidum, which typically fuse as the fetal brain matures. The absence of the CSP, when normally expected, may be associated with neuroanatomic anomalies (Damaj et al., 2010). It may be an isolated finding (Fig. 59.4), but fetal MRI is recommended for further evaluation (Hosseinzadeh et al., 2013). In addition, a larger than expected CSP width should prompt a detailed ultrasound evaluation as this anomaly can be seen in fetuses with aneuploidy (Abele et al., 2013).

Cortical Defects in Size and Organization

Defects in proliferation and neuronal survival include microcephaly and macrocephaly as well as cortical dysplasia. Migration defects result in disruption of the layered cortical structure, which can be seen grossly (as with lissencephaly) or microscopically (focal dysplasia). We will also discuss cortical defects such as heterotopia, PMG, cobblestone cortex, schizencephaly, and other destructive lesions. We will not discuss disorders of neuronal crest migration (e.g., neuroblastoma, Hirschsprung disease).

Projection neurons originate at the periventricular zone and subventricular zones and undergo symmetric and asymmetric cell divisions to populate the neural progenitor cells (reviewed in Lui et al., 2011). The cerebral cortex develops in an inside-out pattern, with early-born cells forming the deepest layers and later-born cells populating the superficial layers. This process occurs during weeks 7 to 11 of gestation. Stop signals direct appropriate arrest of migration and positioning of the final cell layers. Disruption of all of these processes can result in the malformations we discuss (reviewed in Pang et al., 2008). Most interneurons are born in the median ganglionic eminences and migrate tangentially to populate the brain, and the origin of astrocytes and other cell types is under investigation. Brain malformation disorders primarily affecting these cell types have not been described.

These disorders may be genetic or caused by in utero insults (hypoxia, ischemia, metabolic derangements, toxins, and infection), and diagnosis is based on clinical presentation, imaging, pathology, and genetic testing. The malformations may result in epilepsy and intellectual disability and may be part of syndromic disorders with other organ involvement. Management includes both medical and

surgical interventions for seizure control, therapy support for motor and cognitive disabilities, and appropriate surveillance and involvement of specialists if needed. The framework of cerebral cortex development has been used to classify cortical malformations and is being updated on the basis of expanding genetic knowledge (Barkovich et al., 2012).

Cortical Defects in Proliferation and Neuronal Survival

Microcephaly

Disorders caused by abnormal proliferation include microcephaly (small brain) and megalencephaly (large brain). Microcephaly (occipitofrontal circumference greater than two standard deviations [SDs] below the mean) can be defined as primary (evident at birth) or secondary (normal to small occipitofrontal circumference at birth with progression to greater than two SDs below the mean after birth). The causes can be genetic or acquired and may be associated with other extracranial malformations (syndromic microcephaly) or may be an isolated finding. Von der Hagen et al. (2014) described a retrospective cohort of 680 children with microcephaly and found that 28.5% had genetic causes of various types (aneuploidies, de novo copy number variants, autosomal dominant, autosomal recessive, and X-linked). The remaining cases were secondary to injury around or after birth (which can include birth complications, infection, maternal disease, teratogen exposure, infarction, craniosynostosis), but 40% of the cases did not have an identified cause.

Imaging may suggest a normal brain, but oligogyria, gray matter disruption, and hypomyelination may be present microscopically. Patients with microcephaly can also have other cortical malformations, suggesting an overlap in mechanisms. Genetic defects that cause primary microcephaly affect cell cycle progression, cell proliferation, mitotic spindle formation, and DNA repair. The most common genetic causes (such as *ASPM* mutations) affect centrosome function and cell division (Verloes et al., 2013). Secondary microcephaly can be due to postmigrational microcephaly and is associated with a number of syndromes, including Rett and Angleman, and genes involved in protein synthesis and transfer ribonucleic acid synthetases have been implicated (reviewed in Jamuar and Walsh, 2015). Many causes are recessive, so the recurrence risk is often 25%.

Primary microcephaly can be detected in utero by ultrasonography, and when severe, it is associated with a high risk of abnormal neurodevelopmental outcomes. Additional prenatal evaluation may include fetal MRI, infectious evaluation, and genetic testing. Recently, the Zika virus has been implicated as the causative agent of microcephaly in infants whose mothers were exposed to the virus during pregnancy (Plosa et al., 2012; Mlakar et al., 2016). Diagnosis of secondary microcephaly occurs via routine head measurements after birth, and then further evaluation can include brain imaging (ultrasonography or MRI), infectious disease evaluation, and subspecialty consultation (e.g., neurology, genetics, ophthalmology) as indicated.

Prognosis is related to the severity of microcephaly (Ashwal et al., 2009), as well as the presence of other brain abnormalities, somatic malformations, and genetic diagnosis. Developmental disabilities and imaging abnormalities are seen in approximately 80% of children with severe microcephaly, which is defined as a head circumference greater than three SDs below the mean, while the risk is much lower in children with a head circumference greater than two SDs below the mean. Comorbid conditions include intellectual disability, epilepsy, cerebral palsy, and ophthalmologic disorders.

Macrocephaly and Megalencephaly

Macrocephaly refers to a large head size (greater than two SDs above the mean) that can be due to a variety of causes, such as hydrocephalus, thick skull, or megalencephaly (large brain size). Megalencephaly is rare in neonates since it is usually due to increasing brain size over time, but it is often associated with developmental delay and epilepsy (Winden et al., 2015). Increasing head circumference in infancy needs to be followed closely, and imaging should be considered to evaluate the infant for causes of increased intracranial pressure. In the absence of other malformations or neurodevelopmental issues, accelerated head growth with increased extra-axial fluid during the first year or two after birth is generally thought to be benign and may be due to an imbalance in CSF production versus CSF absorption by immature subarachnoid granulations (Neveling and Truex, 1983; Barlow, 1984).

Macrocephaly can be seen in a diverse group of conditions characterized by a large brain, most commonly manifesting itself as an isolated finding in familial and sporadic cases. At birth, the head circumference is greater than 90%. Macrocephaly can also be seen in fragile X syndrome and Klinefelter syndrome and in neuroendocrine disorders (Beckwith–Wiedemann syndrome, cerebral gigantism, and achondroplasia) (DeMeyer, 1972; Dodge et al., 1983). The prognosis and recurrence risk depend on the cause.

The causes of megalencephaly can be divided into metabolic and anatomic categories. Metabolic causes include organic acidurias (e.g., glutaric aciduria), lysosomal storage diseases, and leukoencephalopathies, while anatomic megalencephaly can be due to mutations in genes affecting the pathways involved in cell growth such as *MTOR*, *Ras*/*MAPK*, and *SHH* (reviewed in Winden et al., 2015). In rare cases, megalencephaly is part of a syndrome called *megalencephaly, polymicrogyria, polydactyly, and hydrocephalus (MPPH) syndrome* (Colombani et al., 2006; Pisano et al., 2008). Megalencephaly–capillary malformation (MCAP) syndrome is also part of megalencephaly-related syndromes. Three genes have been implicated: *AKT3*, *PIK3R2*, and *PIK3CA* (Lee and Gleeson, 2010; Riviere et al., 2012; D’Gama, et al., 2015). This spectrum of disorders (including focal cortical dysplasia, hemimegalencephaly, and megalencephaly) are due in part to pathway mutations in the

PI3K/AKT pathway (Jansen et al., 2015). *PIK3CA* is also associated with other overgrowth disorders, including MCAP, but also including congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal/spinal abnormalities (CLOVES) syndrome and fibroadipose hyperplasia (Mirzaa et al., 2013).

Hemimegalencephaly results in overgrowth of partial, one hemisphere, or bilateral overgrowth, resulting in cortical dysplasia, abnormalities of the white matter and cell types, and abnormal gyral patterns. This finding has been associated with a number of genetic syndromes and is associated with intellectual disability and intractable epilepsy, with onset usually in infancy (reviewed in Pang et al., 2008). An improved outcome may be achieved in select patients after hemispherectomy as early as the neonatal period (Battaglia et al., 1999). Hemimegalencephaly may also be associated with neurocutaneous syndromes such as sebaceous nevus syndrome, hypomelanosis of Ito, facial lipoma, and tuberous sclerosis (Montagna et al., 1991; Dodge and Dobyns, 1995; Guerra et al., 2007; Leventer, et al., 2008; Gowda et al., 2015). The prognosis and recurrence risk for macrocephaly and megalencephaly depend on the underlying cause.

Cortical Defects in Migration

In addition to appropriate proliferation, cortical development requires appropriate neuronal migration. Disruption in the initiation, continuation, or arrest of neuronal migration results in a number of disorders, including heterotopia, lissencephaly, and cobblestone cortex. These abnormalities are often accompanied by other malformations, such as hypoplasia or ACC, pointing to a complex interplay between the mechanisms that determine neuronal migration and axon path finding. Structural imaging has identified many defects in radial migration of projection neurons, while defects in tangential migration of interneurons are not typically identified.

Heterotopia

Heterotopia can either be periventricular (suggesting disruption of initiation of migration), subcortical (as in subcortical band heterotopia), caused by misregulation of migration, or transmantle (as seen with injury). Periventricular heterotopia (PVH) is characterized by masses of gray matter adjacent to the walls of the lateral ventricles (Fig. 59.5). Patients often present with partial seizures. Bilateral PVH may be associated with other malformations (such as hypoplasia of the corpus callosum). *FLNA* mutations cause bilateral contiguous PVH in females or rarely in males if they are hemizygous, as this is usually lethal in males. The involvement of the *FLNA* gene suggests a disruption of cell motility as a mechanism for this malformation (reviewed in Leventer et al., 2008). Among cases of familial PVH, 80% have *FLNA* mutations. Twenty percent of sporadic cases have *FLNA* mutations, indicating the importance of environmental influences, or unidentified genetic causes (Lu and Sheen, 2005). Given associated cardiac problems with *FLNA*-related PVH, echocardiogram and cardiac surveillance are recommended. Neurodevelopmental outcomes are varied and may be associated with learning disabilities (Chen and Walsh, 2015). Mutations in *ARFGEF2* have also been identified in patients with PVH (Bardon-Cancho et al., 2014).

Subcortical band heterotopia is characterized by a band of heterotopic gray matter within the white matter (Fig. 59.6). Somatic mutations in *DCX* and *LIS1* have been associated with subcortical band heterotopia (reviewed in Jamuar and Walsh, 2015). Patients typically present with developmental delay, intellectual disability,

• **Fig. 59.5** Magnetic Resonance Image Scan Demonstrating Periventricular Nodular Heterotopia. Periventricular nodular masses (arrowheads) are visualized adjacent to the lateral ventricles in this T2-weighted coronal image. (Courtesy of Dr. Martin Salinsky, Department of Neurology, Oregon Health and Science University, Portland, OR.)

and/or epilepsy but have less severe disability than those with lissencephaly, and 25% have normal or near normal intelligence. Neurologic deficits roughly correlate with the thickness and extent of the subcortical band (Dobyns et al., 1996).

Lissencephaly

The lissencephalies are characterized by reduced or absent gyri, giving the cortical surface a smooth or nearly smooth appearance (Kato and Dobyns, 2003). Patients have intellectual disability, hypotonia, epilepsy, and feeding difficulties (reviewed in Leventer et al., 2008). The classification of the lissencephalies reflects the rapidly evolving molecular basis of these disorders (Barkovich et al., 2001; Jissendi-Tchofo et al., 2009; see Fig. 59.6). Most patients are included in the classic lissencephaly/subcortical band heterotopia spectrum (previously type 1), which is associated with deletions or missense mutations in *LIS1* (Torres et al., 2004). Other associated genes include *DCX* (Hehr et al., 2011), *YWHAE*, and several tubulin genes. These gene products have roles in cell motility, neurogenesis, and microtubule polymerization (des Portes et al., 1998; Gleeson et al., 1998). Mutations in the *ARX* gene, which encodes a transcription factor, result in another X-linked lissencephaly with abnormal genitalia and are characterized by abnormal basal ganglia, immature white matter, and ACC (Kitamura et al., 2002).

Lissencephaly can also be seen with cerebellar hypoplasia (Barkovich et al., 2001; Ross and Walsh, 2001; Kato and Dobyns, 2003; Lu and Sheen, 2005; Jissendi-Tchofo et al., 2009). The most common cause of this phenotype is dominant mutations in several tubulin genes, which can often be distinguished by characteristic basal ganglia, brainstem, and cerebellar dysplasia (Bahi-Buisson and Cavallin, 2016). Less frequently, lissencephaly with a moderately thick cortex, severe global cerebellar hypoplasia, and a malformed hippocampus is caused by recessive mutations in the

RELN gene, which encodes a large extracellular matrix protein involved in signaling via the apolipoprotein E and very low-density lipoprotein receptors (Hong et al., 2000; Ross and Walsh, 2001). Mutations in *VLDLR* cause a milder phenotype with mildly thickened and simplified cortical gyri and cerebellar hypoplasia (Boycott et al., 2005).

Clinical Features

Lissencephaly is diagnosed in utero or patients with lissencephaly present with hypotonia, developmental delay, and/or seizures during infancy. Spasticity may develop later in the first year. Isolated lissencephaly carries a poor long-term prognosis dominated by cognitive disability, spastic quadriplegia, and epilepsy. Craniofacial anomalies can be subtle in patients with *LIS1* mutations or more pronounced as in Miller–Dieker syndrome caused by deletion of *LIS1* and *YWHAE* (Dobyns et al., 1984). Miller–Dieker syndrome is characterized by severe lissencephaly, a high forehead with bitemporal hallowing, short nose, upturned nares, downturned vermian border, and small jaw (Dobyns and Das, 2014). Head circumference is typically normal at birth, but progressive microcephaly occurs during the first year. Neonatal seizures may occur, and severe myoclonic epilepsy typically develops in the latter half of the first year (e.g., infantile spasms or Lennox–Gastaut syndrome) (Guerrini and Carrozzo, 2001).

Cobblestone Complex Syndromes

Cobblestone cortex (previously known as *lissencephaly type II*) is characterized by a nodular appearance of the cortex, which is due to disruption of the normal arrest of cells at the pial surface (reviewed in Pang et al., 2008). On MRI, T2/fluid-attenuated inversion recovery signal is often markedly increased in cortical white matter. Cobblestone cortex is seen in the congenital muscular dystrophies: Walker–Warburg syndrome, muscle–eye–brain disease, and Fukuyama congenital muscular dystrophy (reviewed in Sparks et al., 2012). These autosomal recessive disorders (Cormand et al., 2001) belong to a class of glycosylation-deficient muscular dystrophies, the dystroglycanopathies, that are related to mutations in enzymes that catalyze the posttranslational O-glycosylation of a small number of mammalian glycoproteins (Grewal and Hewitt, 2003; Toda et al., 2005).

Walker–Warburg syndrome is the most severe of the three (Warburg, 1987). Macrocephaly is present at birth or develops in the first year and is due to hydrocephalus. Kinked brainstem, cerebellar hypoplasia, and elevated creatine kinase level are strongly suggestive of the diagnosis. Ocular anomalies include retinal detachment, optic nerve hypoplasia, microphthalmia, and coloboma; muscular weakness is typically severe (Volpe, 2000). Survival beyond the first year is uncommon. The brain malformations and neurodevelopmental outcome in patients with muscle–eye–brain disease are less severe, but patients still have substantial disability and most often experience seizures. Individuals with Fukuyama congenital muscular dystrophy can have variable cortical and eye findings. Hypoplasia, cysts, and PMG can be seen in the cerebellum. Moderate cognitive disability can be seen, and some patients may walk independently (reviewed in Sparks et al., 2012).

Mutations in the laminin subunit β_1 (encoded by *LAMB1*), which localizes to the pial basement membrane, also result in cobblestone cortex and other brain conditions, but these malformations do not exhibit the ocular or muscular abnormalities seen in the syndromes mentioned above (Radmanesh et al., 2013). Similarly, *GPR56* mutations can cause a recessive syndrome with

• **Fig. 59.6** Classic Lissencephaly/Subcortical Band Heterotopia Spectrum. (A) Axial T2-weighted magnetic resonance image (MRI) of the brain in a child with *LIS1* mutation. (B) Axial T2-weighted MRI of the brain in a child with a *TUBA1A* mutation. (C) Histologic specimen demonstrating the presence of a broad band of heterotopic gray matter (*arrow*) that is situated within the cerebral white matter and distinct from the cerebral cortex (*asterisk*) in a female patient with a *DCX* mutation. (D) T1-weighted axial MRI demonstrating the circumferential nature of the subcortical band heterotopia (*arrows*) in another female patient with a *DCX* mutation. (Courtesy of Dr. Joseph G. Gleeson, Department of Neurology, School of Medicine, University of California, San Diego, CA; M. Elizabeth Ross, Department of Neurology, University of Minnesota, Minneapolis, MN; Christopher A. Walsh, Department of Neurology, University of Minnesota; and Christopher A. Walsh, Department of Neurology, Harvard Medical School, Boston, MA.)

cobblestone-like cortex, abnormal white matter signal, and cerebellar cysts (Quattrocchi et al., 2013). Bilateral frontoparietal PMG may be associated with mutations in the G protein-coupled receptor 56 (Piao et al., 2002). Neuroimaging shows bilateral white matter changes, small brainstem, and small dysmorphic cerebellum, which is unique for the PMG syndromes (Chang, et al., 2003; Barkovich, 2010).

Polymicrogyria

PMG was originally defined by histopathologic findings. With the advent of brain MRI, the term is now commonly used to refer to a variety of appearances with an irregular gray-white border and many very small gyri or a thickened cortical ribbon (Fig. 59.7). PMG or PMG-like appearances can be caused by mutations in a

• **Fig. 59.7** Spectrum of Findings With Polymicrogyria. T2-weighted axial images (A-C) showing the varied magnetic resonance findings with polymicrogyria: (A) frontal and perisylvian polymicrogyria; (B) predominantly perisylvian; (C) globally thickened cortex.

variety of genes, as well as by infection (CMV, toxoplasmosis), ischemic/vascular anomalies, and metabolic disorders. A variety of other malformations, such as schizencephaly, can be seen in association with PMG. Recently, some ischemic etiologies have been found to be genetic in origin (*OCN* or *COL4A1* mutations, 22q11 deletions, and Sturge–Weber syndrome) (Squier and Jansen, 2014).

Historically, two major types of PMG have been proposed: layered and unlayered. *Layered PMG* has four rather than six distinct cortical layers. This “classic” form is localized adjacent to regions of encephalomalacia and is thought to be frequently caused by injury. *Unlayered PMG* is cortex that lacks distinct cortical layers and is associated with other migrational disturbances, such as subcortical nodular heterotopia, lissencephaly, and schizencephaly. More recently, multiple types of PMG have been demonstrated in the same patient (Judkins et al., 2011), and the term has been used to refer to a variety of appearances on structural MRI without correlation to pathologic findings (see Fig. 59.7). PMG is usually sporadic, but it can be seen in association with several syndromes, especially if it is bilateral, and also has been seen in multiple modes of inheritance in rare familial cases (Barkovich et al., 1999; Ross and Walsh, 2001).

Clinical Features

The clinical presentation relates to the extent of cortical dysplasia and the underlying cause but is difficult to predict on the basis of imaging findings alone. Bilateral PMG or involvement of more than half of a single hemisphere carries a high risk of moderate-to-severe developmental disability and significant motor dysfunction (Barkovich et al., 2005). Hemiparesis or quadriplegia is often seen. Refractory epilepsy with partial complex seizures or multiple generalized seizure types may be delayed in onset beyond the neonatal period.

Bilateral perisylvian PMG is the most commonly observed pattern. Patients with bilateral perisylvian PMG are likely to have epilepsy and intellectual disability (Guerrini et al., 1992; Kuzniecky et al., 1993; Guerreiro et al., 2000). In bilateral frontoparietal PMG, patients have global developmental delay, dysconjugate gaze/

esotropia, and bilateral pyramidal and cerebellar motor signs (Chang et al., 2003).

Tubulinopathy-Related Dysgyria

Mutations in α - and β -tubulin genes have been implicated in a range of cortical malformations (Cushion et al., 2013). Mutations in six tubulin genes have been shown to cause tubulinopathies usually because of de novo dominant mutations, with rare examples of recurrence caused by germline mosaicism (Bahi-Buisson and Cavallin, 2016). A more subtle malformation, called *tubulinopathy-related dysgyria*, shows a subtle irregular cortical gyral pattern with basal ganglia and brainstem dysplasia, associated with *TUBA1A*, *TUBB2B*, and *TUBB3* mutations that occur de novo or are inherited from a mosaic parent (Oegema et al., 2015). Patients can present with motor, cognitive, and language delay that can be mild, abnormal eye movements, behavioral issues, and seizures.

Destructive Lesions

Schizencephaly, porencephaly, and hydranencephaly are malformations that result from destructive lesions during development. Schizencephaly may be unilateral or bilateral and “open-lipped” or “closed-lipped” (Fig. 59.8). When it is severe, both lateral ventricles communicate widely with the extra-axial space (bilateral open-lipped). Unsurprisingly, patients have significant cognitive, motor, and communication difficulties, and epilepsy is common (reviewed in Granata et al., 2005). The severity of the epilepsy is not correlated with the severity of the brain malformation, and two studies found that patients with unilateral schizencephaly had earlier age of seizure onset and more refractory epilepsy than those with bilateral schizencephaly (Granata et al., 1996; Denis et al., 2000). Diagnosis is by MRI, and the findings may include other brain malformations, such as cortical dysplasia, corpus callosum dysgenesis, and absent septum pellucidum. Presumed causes include destructive events such as ischemia and infection. Recurrence within rare families suggests a genetic origin (reviewed in Leventer et al., 2008). Schizencephaly may also result from an extreme failure of

• **Fig. 59.8** Magnetic Resonance Image Scan Demonstrating Bilateral Open-Lip Schizencephaly. (A) Axial T1-weighted image. Note that the bilateral clefts (arrows) extend to the lateral ventricles. (B) Coronal T1-weighted image. Note that the clefts (arrows) are lined with gray matter (asterisks). (Courtesy of Dr. A. James Barkovich, Department of Radiology, School of Medicine, University of California, San Francisco, CA.)

neurons to migrate. This is supported by histology showing that the schizencephalic cleft has features of a migrational disturbance, such as large neuronal heterotopia bordered by adjacent PMG (Bird and Gilles, 1987). Pituitary insufficiency is seen in a substantial subset of patients, particularly if optic nerve hypoplasia is also present.

Porencephaly is a fluid-filled cavity within the cerebral hemispheres, caused by loss of tissue secondary to trauma, infection, or hemorrhage. This can develop prenatally and postnatally. Mutations in *COL4A1* are associated with an autosomal dominant form of hereditary porencephaly. Mutations in *COL4A1* can also cause lesions of the kidneys, eyes, cardiac muscle, or skeletal muscle (reviewed in Meuwissen et al., 2015). *COL4A2* has been associated with familial and sporadic porencephaly. These two genes encode collagen subunits that help form the basement membrane. It is felt that collagen-related porencephaly is secondary to vascular

events. *COL4A1* and *COL4A2* mutations can be associated with stroke and other highly variable manifestations in family members with the same mutation, so the affected infant and at-risk family members should undergo neurologic, ophthalmologic, renal, and cardiac screening.

Hydranencephaly is due to replacement of the hemispheres with a fluid-filled sac and may be considered an extreme form of porencephaly. This rare condition has a number of proposed mechanisms, including infarction, leukomalacia, necrosis, and infection versus thrombotic material from a cotwin. In addition to the etiologies previously mentioned, there may be an association of destructive lesions, such as porencephaly, hydranencephaly, and schizencephaly, with in utero exposure to vasoactive drugs such as cocaine, heroin, and methamphetamine (Eller and Kuller, 1995).

A rare genetic disorder called *Fowler syndrome*, caused by mutations in *FLVCR2*, causes severe hydrocephaly but also hypokinesia, CNS vasculopathy, and arthrogryposis. This disorder is also called *proliferative vasculopathy and hydranencephaly–hydrocephaly (PVHH) syndrome*. Although Kvarnung et al. (2016) described two siblings that survived beyond infancy, most infants do not live beyond the first year (Gentry and Connell, 2013). Hydrocephalus and feeding difficulties are frequent complications, and decisions about whether to treat the infant with CSF diversion or tube feeding can be difficult given the limited developmental potential and life span.

Malformations of Structures in the Posterior Fossa

Normal Midbrain and Hindbrain Development

The brainstem comprises the midbrain, pons, and medulla, while the cerebellum is composed of a vermis and hemispheres. The development of these structures occurs after closure of the neural tube and coincides with prosencephalic development (Ten Donkelaar and Lammens, 2009). The development of the cerebellum, like that of the cortex, is influenced by both intrinsic (genetic) and extrinsic (inductive/environmental) factors (Leto et al., 2016). The midbrain structures derive from the mesencephalon and myelencephalon, and the hindbrain derives from the rhombencephalon by gestational week 4. The cerebellar vermis derives from both the caudal third of the mesencephalon and the hindbrain (Shekdar, 2011). Cerebellar development continues into the second postnatal year, making the cerebellum particularly vulnerable in premature infants. The posterior fossa is evaluated by ultrasonography or MRI during the second and third trimesters of pregnancy, but MRI is the modality of choice if abnormalities are suspected (Bosemani et al., 2015).

For this section, we will characterize posterior fossa malformations on the basis of imaging findings (Doherty et al., 2013). Embryonic and genetic classifications have been used (Barkovich et al., 2007, 2009). Alternatively, posterior fossa malformations can be classified on the basis of inherited (metabolic, structural, neurodegenerative, or the spinocerebellar ataxias) versus acquired causes (vascular, hypoxic-ischemic encephalopathy infection, disrupted development, toxic, neoplastic, or teratogenic) (Klein et al., 2016). Clinical features of posterior fossa abnormalities are nonspecific but include hypotonia, developmental delay, nystagmus, and decreased visual attention. Depending on the malformation, seizures and apnea may also be present, as may evidence of cranial nerve dysfunction. The combination of clinical, imaging, and genetic testing information is required for accurate diagnosis.

Malformations With Major Cerebellar Involvement

Dandy–Walker Malformation

Dandy–Walker malformation (DWM) is typified by aplasia or hypoplasia of the vermis of the cerebellum, cystic dilation of the fourth ventricle, and enlargement of the posterior fossa with upward displacement of the lateral sinuses, tentorium, and torcular (Benda, 1954; D’Agostino et al., 1963; Hart et al., 1972; Friede, 1989; Fig. 59.9). The brainstem may be affected by hypoplasia of the pons (Shekdar, 2011). Diagnosis can occur in utero by ultrasonography and fetal MRI. Prenatal ultrasonography and MRI are increasingly used, but both have continued challenges for the precise anatomic definition of these malformations (Malinge et al., 2009). The enlargement of the posterior fossa and displacement of its contents may be related to communication of the fourth ventricle with a retrocerebellar cyst, often of considerable size. Hydrocephalus

is also a common feature that may present in the neonatal period with macrocephaly (Hart et al., 1972; Costa and Hauw, 1995).

Epidemiology and Etiology

Estimates of the prevalence of DWM are affected by the lack of agreement regarding the definition of DWM. DWM appears to occur in at least 1 in 5000 liveborn infants (Parisi and Dobyns, 2003). DWM may be isolated or associated with a number of syndromes (e.g., Walker–Warburg syndrome, Meckel syndrome) as well as trisomies 9, 13, and 18. Given the low recurrence risk of 1%–3%, DWM is likely due to de novo mutations, environmental insults, and vascular and multifactorial causes. Mutations in *FOXC1* and *ZIC1/ZIC4* have been identified in small numbers of patients, but in general a specific genetic cause cannot be identified.

Clinical Features and Management

DWM can be associated with other brain imaging abnormalities, particularly ACC and hydrocephalus. In addition, cardiac and

• **Fig. 59.9** Posterior Fossa Abnormalities. Sagittal images of a normal brain (A), the brain of a child with Joubert syndrome (B), and the brain of a child with Dandy–Walker malformation (C) illustrate the features of these hindbrain malformations. Note the presence of cerebellar vermis hypoplasia (arrow) in both (B) and (C). By contrast, the patient with Joubert syndrome (B) has only a slightly enlarged fourth ventricle, whereas in the Dandy–Walker malformation (C) the fourth ventricle is massively dilated. (D, E) Molar tooth sign. Comparison of axial images from a normal brain (D) with that of a child with Joubert syndrome (E). Note two key features of the molar tooth sign: a deepened interpeduncular fossa (arrow) and the elongated superior cerebellar peduncles (arrowhead). ([A–C] Courtesy of Dr. Joseph G. Gleeson, Department of Neurology, School of Medicine, University of California, San Diego, CA, and Dr. William B. Dobyns, University of Chicago School of Medicine, Chicago, IL; [D, E] courtesy of Dr. Joseph G. Gleeson, Department of Neurology, School of Medicine, University of California, San Diego, CA.)

• **Fig. 59.10** Rhomboencephalosynapsis as Demonstrated by Magnetic Resonance Imaging. (A) T1-weighted sagittal image showing excessive white matter centrally in the cerebellum and absent primary and horizontal fissures. The T2-weighted coronal (B) and axial (C) show continuous folia across the midline and the smooth dorsal cerebellar surface caused by vermian agenesis and hemisphere fusion.

other organ malformations can be present. Management is similar to that for other neurodevelopmental conditions and can include surgical correction of hydrocephalus with shunt placement within the lateral ventricles and/or posterior fossa. The outcome is broad, with higher risk of abnormal neurodevelopmental outcome in patients with additional malformations and specific genetic conditions.

Rhomboencephalosynapsis

Rhomboencephalosynapsis (RES) is unique among the cerebellar vermis hypoplasias. Instead of the cerebellar hemispheres being widely separated, the hemispheres, white matter, and deep cerebellar nuclei are variably fused (Paprocka et al., 2012; Fig. 59.10). Clinically, patients with RES may present with ataxia, muscle hypotonia, abnormal eye movements, dysarthria, head shaking, and developmental delay with variable severity. RES may be isolated or seen in combination with other syndromes such as vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies (VACTERL) and may be associated with other CNS abnormalities, such as hydrocephalus (Ishak et al., 2012; Tully et al., 2012; Poretti and Boltshauser, 2015). No definitive causes have been identified, but proposed causes include genetic defects and environmental factors (such as maternal diabetes and other exposures) (Paprocka et al., 2012).

RES can be diagnosed prenatally by fetal MRI and should be suspected in fetuses with ventriculomegaly and cerebellar hypoplasia identified by ultrasonography. In the absence of ventriculomegaly or other imaging abnormalities, RES is rarely diagnosed prenatally. In addition, when aqueductal stenosis is suspected prenatally or postnatally, the cerebellum should be closely scrutinized for RES (Ishak et al., 2012).

Malformations With Both Cerebellar and Brainstem Involvement

Joubert Syndrome and Related Disorders

Joubert syndrome (JS) is an autosomal recessive disorder usually presenting with hypotonia, abnormal eye movements, and

developmental delays. The prevalence has been estimated to be 1 in 100,000. Apnea and tachypnea may be notable in infancy (Romani et al., 2013), and early presentation may include head titubation (Poretti et al., 2014), which is a subtle nodding of the head seen in JS and other posterior fossa malformations. JS is related to a number of other disorders that can be defined by the “molar tooth sign” on imaging (see Fig. 59.9): cerebellar vermis hypoplasia/aplasia, deep interpeduncular fossa, and thick, elongated superior cerebellar peduncles. Disorders with the molar tooth sign on imaging have associated gene products related to ciliopathies, suggesting a common pathway. Historically, several other names have been used to refer to JS, including cerebellar ocular renal syndrome, cerebellar hypoplasia/aplasia, oligophrenia, cerebellar vermis hypoplasia/aplasia, oligophrenia, congenital ataxia, ocular coloboma, and hepatic fibrosis (COACH) syndrome, and Varadi–Papp syndrome (Sattar and Gleeson, 2011). Mutations in more than 30 genes have been identified in more than 50% of patients with JS (Parisi and Glass, 2013), with five genes accounting for approximately 40% of patients (*AHI1*, *CC2D2A*, *CEP290*, *TMEM67*, and *C5ORF42*) (Bachmann-Gagescu et al., 2015). Distinguishing JS from other hindbrain malformations is essential, since the recurrence risk is 25%, and substantial subsets of patients develop progressive retinal dystrophy, fibrocystic kidney disease, and liver fibrosis, requiring lifelong monitoring and treatment. Some genetic causes are associated with higher risk of complications (e.g., loss of *CEP290* is associated with retinal dystrophy), therefore genetic testing can be used to guide monitoring (Bachmann-Gagescu et al., 2015).

Pontocerebellar Hypoplasia

Pontocerebellar hypoplasia (PCH) is a diverse group of largely autosomal recessive disorders characterized by a variable degree of pons and cerebellar hypoplasia (Fig. 59.11). Ten overlapping subtypes have been proposed, many presenting in the neonatal period (reviewed in Klein et al., 2016). PCH can occur in association with congenital disorders of glycosylation, mitochondrial diseases, and congenital muscular dystrophies. Multiple genetic causes have been identified, most commonly mutations in *TSEN54*, but up to 40% of patients do not have an identified cause (Dyment et al.,

• **Fig. 59.11 Pontocerebellar Hypoplasia.** (A) T1-weighted sagittal and (B) T2-weighted coronal images of a patient with *TSEN45*-related pontocerebellar hypoplasia (PCH). *TSEN54* mutations have been identified in PCH types 1, 2, 4, and 5 and can be associated with additional malformations, including atrophic cortex and cerebellar hemisphere hypoplasia more than vermin hypoplasia, cerebellar hemisphere more than vermin hypoplasia. (C) T1-weighted sagittal and (D) T1-weighted coronal images of a patient with *CASK*-related PCH. *CASK*-related PCH may be associated with mild small pons and cerebellum, with proportionate hypoplasia of the cerebellar vermis and hemispheres.

2013). Given the phenotypic and genetic overlap in these subtypes, use of a combination of genetic, clinical, and imaging findings is more specific in describing these disorders (Table 59.1; Aldinger and Doherty, 2016). In patients with *TSEN*-related PCH, the vermis is often relatively preserved compared with the hemispheres, in contrast to most other PCH disorders. Outcome data are sparse and depend somewhat on the type of PCH, but typically patients have significant developmental delays, tone abnormalities, feeding issues, and respiratory compromise (Klein et al., 2016).

Malformations With Brainstem Involvement

Moebius Sequence Disorders

A number of disorders fall under the congenital cranial dysinnervation disorders, which are sporadic or familial neuromuscular disorders involving abnormal eye, eyelid, or facial movement caused by primary or secondary dysinnervation of cranial nerves. Moebius sequence represents a group of disorders with unilateral or bilateral

TABLE 59.1 Pontocerebellar Hypoplasia*

| Pontocerebellar Hypoplasia | Clinical Findings | Radiologic Findings | Associated Genes (Major Listed First) |
|----------------------------|---|--|--|
| Type 1 | Spinal muscular atrophy | Mild hypoplastic pons, with proportional hypoplasia of the vermis and hemispheres | <i>EXOSC3</i> , <i>RARS2</i> , <i>TSEN54</i> , <i>VRK1</i> |
| Type 2 | Neonatal encephalopathy, progressive microcephaly, increased tone, dyskinesia, seizures, cortical visual impairment | Postmigrational microcephaly, small pons and cerebellum, atrophic cortex with thin corpus callosum, vermis less affected than hemispheres | <i>TSEN54</i> , <i>TSEN2</i> , <i>TSEN34</i> |
| Type 3 | Hypotonia, hyperreflexia, infantile seizures, developmental delay | Small pons and cerebellum, reduced amount of cerebral white matter | <i>PCLO</i> |
| Types 4 and 5 | Severe type 2 | As type 2 | <i>TSEN54</i> , <i>TSEN2</i> , <i>TSEN34</i> |
| Type 6 | Elevated CSF lactate level | Small pons and cerebellum, vermis affected more severely than hemispheres | <i>RARS2</i> |
| Type 8 | Acquired microcephaly, increased tone and contractures, moderate to severe developmental delay | Small pons and cerebellum with proportionate hypoplasia of the vermis and hemispheres | <i>CHMP1A</i> |
| Type 9 | Progressive microcephaly, seizure onset in infancy, hypertonia, and visual impairment. Severe developmental delay | Small cerebellum with atrophy, pons with ventral flattening, mega cisterna magna and brainstem with a figure-of-eight appearance, atrophy of cerebral cortex, and corpus callosum hypoplasia | <i>AMPD2</i> |
| Type 10 | Progressive microcephaly and neurodegeneration by 6 months, absent or delayed speech, progressive spasticity, spontaneous seizures, severe developmental impairment | Small cerebellum, pons, and corpus callosum with atrophy | <i>CLP1</i> |

facial weakness, loss of abduction of the eye, and other cranial nerve dysfunction and may also include orofacial malformations, limb anomalies, and chest wall anomalies (Briegel, 2006; Oystreck et al., 2011; Gutowski and Chilton, 2015).

Moebius sequence disorders have a prevalence of 2 in 10,000 to 20 in 10,000 (reviewed in Briegel, 2006). Moebius sequence may be secondary to an ischemic event affecting the tegmental watershed zone (Sarnat, 2004). Other vascular causes may include disruption of primitive subclavian arteries before establishment of the blood supply to the brainstem. This may be represented by calcifications in the brainstem (Briegel, 2006).

A number of teratogens have been implicated in Moebius sequence, including hyperthermia, electric shock, alcohol, drugs (benzodiazepines, alcohol, and cocaine), and medications such as misoprostol (da Silva Dal Pizzol et al., 2006). A number of genes have been hypothesized to play a role, including *MBS1*, *MBS2*, and *MBS3*. Infants may have feeding difficulties, requiring special bottles or tube feeding. Given the association with Kallman syndrome, evaluation of the heart and renal system is needed. Management includes therapies for feeding, speech, and other issues, as well as surgical remediation of nerve and muscle abnormalities. Challenges for older children include speech, language, and intellectual disabilities and autism (Briegel, 2006).

HOXA1A Mutation Syndromes

Mutations in *HOXA1*, which encodes a transcription factor, have been found to cause two related syndromes: Bosley–Salih–Alorainy syndrome in a Saudi Arabian family (and a Turkish individual) and Athabascan brainstem dysgenesis syndrome in an Athabascan Native American population (Erickson, 1999). Bosley–Salih–Alorainy syndrome is typified by bilateral Duane retraction syndrome type 3, deafness, cerebral vascular malformations, and autism, while Athabascan brainstem dysgenesis syndrome presents with horizontal gaze restriction, deafness, intellectual disability, weakness, central hypoventilation, cerebral vascular malformations, and cardiac malformations. Not all patients have horizontal gaze restriction or hearing difficulties. Bilateral Duane retraction syndrome or heart anomalies may be the sole representation of *HOXA1* mutations, and other clinical manifestations may cooccur (such as deafness, autism, and cerebrovascular abnormalities) (Bosley et al., 2008).

Chiari Malformations

Historically, three numbered types of Chiari malformations have been defined, but they are not etiologically related.

Chiari type I malformation is characterized by inferior ectopia of the cerebellar tonsils into the spinal canal, often with compression

of the tonsils and restricted CSF flow. It is uncommonly diagnosed in neonates. Diagnosis is based on clinical and imaging findings; patients may have headache and lower cranial nerve, cerebellar, and brainstem dysfunction. Herniation of the tonsils greater than 5 to 10 mm in the presence of symptoms is diagnostic, but similar herniation can be seen in the absence of symptoms. Other findings include syringomyelia and scoliosis (Cotes et al., 2015). Mild inferior tonsillar ectopia without compression of the tonsils or restricted CSF flow is common and is not usually associated with symptoms. Chiari type I malformation may be either congenital or acquired: the congenital form presents in children and young adults, while the acquired form may have a later onset. In acquired Chiari malformations the posterior fossa size is normal.

Chiari type II malformation is seen almost exclusively in association with open neural tube defects (NTDs) and is defined by displacement of the cerebellar vermis, medulla, and fourth ventricle into the spinal canal and is associated with a small posterior fossa and frequently hydrocephalus. MRI can be used to confirm these findings and often demonstrates cerebellar hypoplasia and ACC, although these features have not been associated with a higher risk of neurodevelopmental issues. Rarely, migration defects, HPE, and interhemispheric cysts can also be seen (Cotes et al., 2015).

The term *Chiari type III malformation* has been used to refer to a variety of hindbrain malformations that include occipital encephalocele and often kinking of the brainstem or cervical spinal cord. In the absence of good diagnostic criteria and associated outcome data, we recommend referring to specific features in each patient. The medical literature on outcomes is extremely limited, but several reported patients have had limited life span and substantial disability.

Neural Tube Defects and Spinal Cord Dysraphisms

Open NTDs result from a failure of primary neural tube closure during the fourth week of gestation (Roessmann, 1995). Anencephaly results from failure of anterior neuropore closure, while myeloschisis and myelomeningocele (MMC) result from failure of posterior neuropore closure. Craniorachischisis totalis occurs with complete failure of neural tube closure and typically results in spontaneous abortion during embryogenesis or early fetal development. The remainder of the NTDs to be discussed result in malformations of the CNS and the overlying axial skeleton, meninges, and skin that are associated with various degrees of viability in the newborn period.

Epidemiology and Etiology

NTDs remain one of the most common congenital malformations encountered in newborns, with 0.5 to 2 in 1000 pregnancies affected worldwide (Mitchell, 2005; Au et al., 2010). The prevalence differs widely and is particularly influenced by ethnicity, geographic area, and socioeconomic status (Frey and Hauser, 2003). In the United States, for example, the risk of NTDs is higher in people of Hispanic descent but lower in people of African-American descent. After the first affected pregnancy, the risk of recurrence increases at a disproportionately higher rate with each subsequent pregnancy. The risk may nearly triple after each subsequent pregnancy (Elwood et al., 1992).

A marked decline in birth prevalence of both anencephaly and spina bifida has occurred in recent decades. In 1960 the prevalence

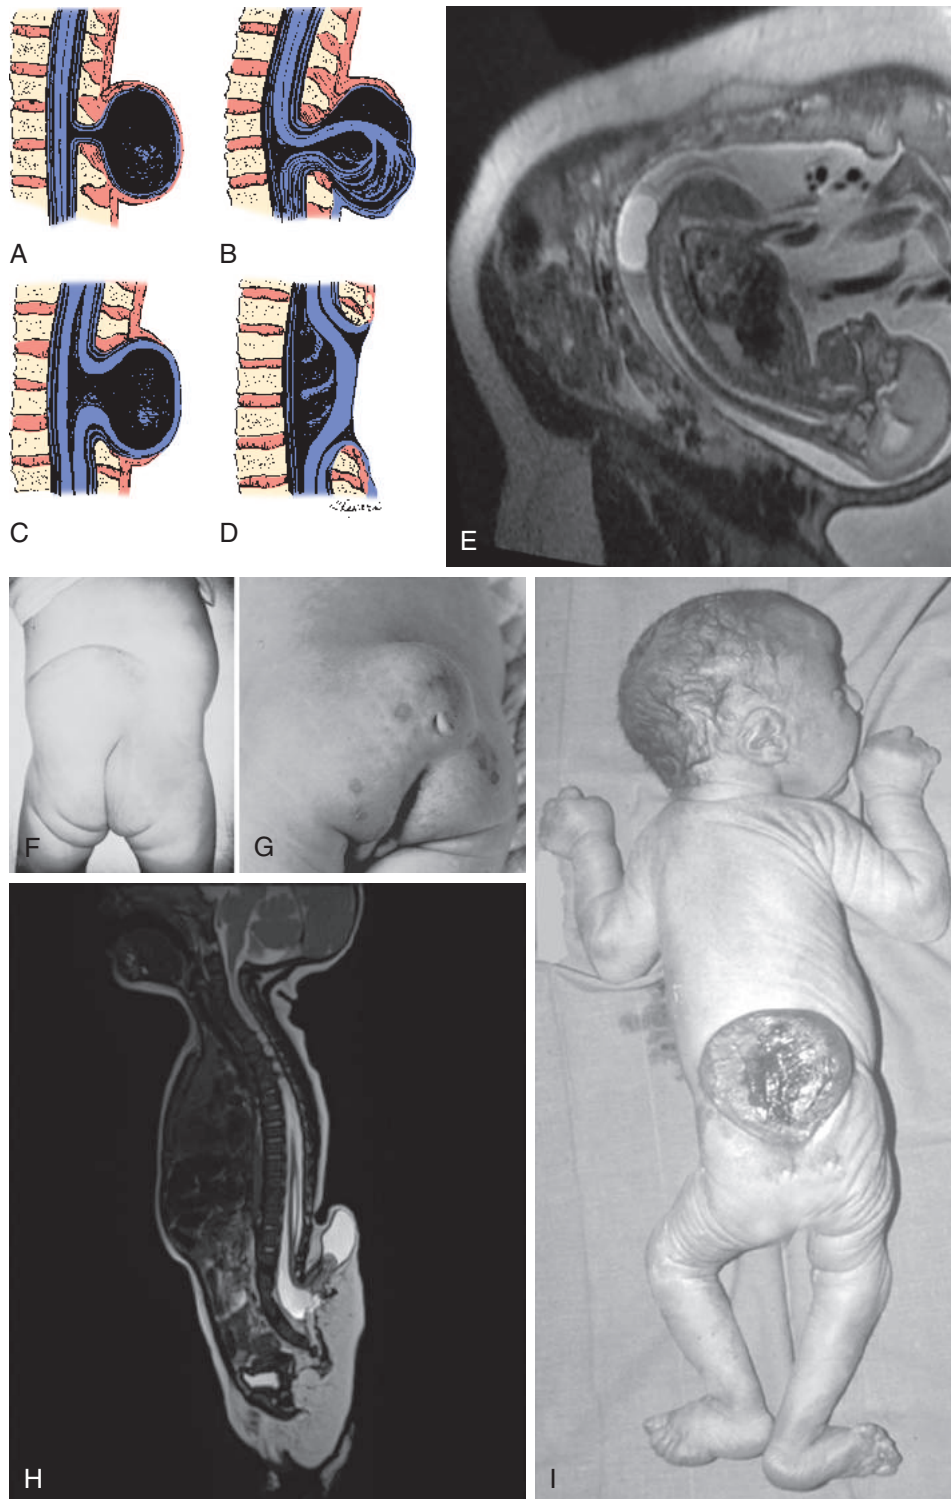

for England and Wales was about 6 in 1000 births; in 1990 this rate dropped to about 1 in 1000. The lower rates reflect two major interventions: in utero diagnosis with termination of affected pregnancies and maternal periconceptional folate therapy. Maternal folate therapy is estimated to prevent approximately 60%–70% of NTDs (Smithells et al., 1981; Czeizel and Dudas, 1992; MRC Vitamin Study Research Group, 1991; Oakley et al., 1994; Castilla et al., 2003; Frey and Hauser, 2003; Mills and Signore, 2004; Zohn and Sarkar, 2008). Approximately 200 genes are known to be required for neurulation, many of which are involved in folic acid metabolism or transport (Harris and Juriloff, 2007). Yet, up to one-third of NTDs are not prevented by folic acid therapy, so a combination of interventions may be required to optimally prevent NTDs (Greene and Copp, 2014), and other factors need to be considered. For example, inositol deficiency can also trigger NTDs in rodent models, and inositol supplementation prevents a significant proportion of these defects (reviewed in Greene et al., 2017). Inositol therapy may reduce the risk of developing gestational diabetes, may improve the metabolic state of the mother, and has not been associated with complications (Noventa et al., 2016). Yet, only folate supplementation is currently recommended for women of childbearing age in the United States (U.S. Preventive Services Task Force, 2009). Most countries now recommend a healthy diet and folate supplementation before conception through the 12th week of pregnancy, with additional supplementation based on risk (Gomes et al., 2015).

Gene–Environment Association of Neural Tube Defects

The etiology of NTDs is complex and multifactorial, and both genetic and environmental factors interact to determine risk; most defects occur sporadically (Blom 2009; Au et al., 2010). Environmental risk factors linked to NTDs include maternal hyperthermia, hyperglycemia, lower socioeconomic status, dietary factors, and prenatal exposure to a number of drugs, including antiepileptic medications such as valproate and carbamazepine (Jones et al., 1989; Frey and Hauser, 2003; Yerby, 2003; Blom, 2009; Au et al., 2010; Wilde et al., 2014). In addition, the fungal toxin fumonisin has been associated with NTDs. A fourfold to fivefold higher prevalence of NTDs occurred in a Mexican-American population because of fumonisins in corn flour used to make tortillas (Suarez et al., 2012; Wilde et al., 2014). NTDs have been associated with genes implicated in diabetes mellitus, obesity, and glucose and oxidative stress. Also, epigenetic mechanisms (such as histone modification, methylation, and nucleosome remodeling) may play a role in neurulation (Wilde et al., 2014).

Fetal Diagnosis of Neural Tube Defects

Diagnosis of open NTDs may be suspected in the case of maternal serum elevation of alpha fetoprotein (AFP) level and can be confirmed by fetal ultrasonography or MRI (Fig. 59.12; Cameron and Moran, 2009). AFP screening is designed to detect open NTDs and Down syndrome (Anderson and Brown, 2009). The optimal time for determination in maternal serum is at 16 to 18 weeks' gestation and in amniotic fluid is at 14 to 16 weeks' gestation. In open NTDs (anencephaly, open spina bifida, and open encephalocele), fetal AFP leaks directly into the amniotic fluid, indirectly increasing maternal serum protein levels. By contrast, skin-covered NTDs are not associated with elevated maternal serum AFP level (Milunsky et al., 1980). A false-positive AFP result can

• **Fig. 59.12 Neural Tube Defects.** (A) Meningocele. Through the bony defect (spina bifida), the meninges herniate and form a cystic sac filled with spinal fluid. The spinal cord does not participate in the herniation and may or may not be abnormal. (B) Myelomeningocele. Spina bifida with myelomeningocele; the spinal cord is herniated into the sac and ends there or may continue abnormally further downward. (C) Myelocystocele or syringomyelocele. The spinal cord shows hydromyelia; the posterior wall of the spinal cord is attached to the ectoderm and undifferentiated. (D) Myelocele. The spinal cord is araphic; a cystic cavity is in front of the anterior wall of the spinal cord. (E) Fetal magnetic resonance image of lumbosacral dysraphism. Note the ventriculomegaly and crowded posterior fossa. (F–H) Three examples of skin-covered neural tube defects. (F, G) Lesion presented in the left buttock as a firm, well-circumscribed, lobulated tumor that became tense when the infant cried. (G) Macular erosions and a congenital skin tag and dimple over the surface. This last feature may be a pilonidal dimple displaced by the tumor. (H) T2-weighted image of a lipomyelomeningocele. (I) Newborn with a large thoracolumbar myelomeningocele. The distal musculature in the lower extremities was weak. ([A–D] From Benda CE. *Developmental Disorders of Mentation and Cerebral Palsies*. New York, NY: Grune and Stratton; 1952; [F–H] courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University, Portland, OR.)

occur with misdating of the fetus (if older than predicted) and a multiple-gestation pregnancy (Brock, 1976). Other causes of a high maternal serum AFP level include contamination of the amniotic fluid by fetal blood (which may occur in cases of esophageal and duodenal atresia), omphalocele, gastroschisis, congenital nephrosis, polycystic kidneys, renal agenesis, annular pancreas, or fetal demise.

Ultrasonography can be used as early as the end of the first trimester for evaluation of the radiographic signs of NTDs, but more typically the diagnosis is made during the second trimester. Abnormal head and cerebellar shape (the “lemon” and “banana” signs) are more sensitive ultrasound indicators for NTD diagnosis than spinal imaging findings. Historically, fetal MRI has not been superior to ultrasonography for identifying the spinal cord defect; however, for those patients electing to have in utero surgery, MRI is used for surgical planning.

Open Neural Tube Defects

Typically, NTDs are characterized as either open lesions (craniorachischisis, anencephaly, MMC, or myelochisis) or closed lesions (see later).

Anencephaly

Anencephaly results after failed anterior closure where exencephaly converts to anencephaly by degradation of the neural tissue (Copp et al., 2013). This is the severest disorder of anterior neural tube closure. Anencephaly accounts for roughly half of all open NTDs (Au et al., 2010). As an early neurulation defect, it occurs no later than 24 days' gestation. Anencephaly can be diagnosed by fetal ultrasound examination (Fig. 59.13) during the first or second trimester (Goldstein and Filly, 1988; Crane, 1992); it is frequently associated with polyhydramnios (Nichols and Schrepfer, 1966).

Anencephaly most commonly involves the forebrain and upper brainstem. It is characterized by absence of the calvaria, and the intracranial contents are replaced by vascularized, disorganized glial tissue (area cerebrovasculosa) (Menkes, 1991; Roessmann, 1995). The hypothalamus and cerebellum are usually malformed,

the anterior lobe of the pituitary is present, and the internal carotid arteries are hypoplastic, which may be secondary to abnormal brain formation. Because the anencephalic infant has a period of exencephaly, where brain tissue extrudes through the unformed calvaria and is degraded by exposure to the amniotic fluid, some investigators have hypothesized that the primary defect is the abnormal skull formation. There are some cases in which remnants of calvarial bones are present, with brain tissue under the protective bones (Roessmann, 1995).

Most neonates are stillborn, and the physical examination is notable for a lack of the brain and cranial vault (Copp et al., 2013). Liveborn neonates live less than 1 or 2 months at the most (Baird and Sadovnick, 1984; Peabody et al., 1989). Without intensive care, survival has not been reported beyond the neonatal period. In a series of 211 women who reported choosing to deliver fetuses with an in utero diagnosis of anencephaly, 72% were liveborn, approximately 67% of the liveborn infants died within 24 hours, and six infants lived for 6 days or more (maximum of 28 days). This study suggested that continuation of pregnancy is a preferred option for some women after they have been counseled about the expected outcomes (Jaquier et al., 2006).

Myelomeningocele

MMC and other associated malformations of the spinal cord arise from failure of posterior neuropore closure, probably no later than day 26 of gestation. Open spinal NTDs are exposed lesions on the back without vertebral or dermal covering (see Fig. 59.12; Menkes, 1991). The spectrum of these spinal cord malformations includes MMC and meningocele. MMC is characterized by herniation of the meninges and spinal cord at the site of the defect. MMCs are about four times more common than meningoceles (skin-covered lesion) (Friede, 1989; Menkes, 1991) and most often occur in the lumbar or lumbosacral regions.

The diagnosis is usually made prenatally by ultrasonography and/or increased AFP level (reviewed in Copp et al., 2013). MMC is usually accompanied by other clinically significant CNS abnormalities, including Chiari type II malformation and hydrocephalus (Del Bigio, 2010). On the basis of historical data, 60% of patients with occipital, cervical, thoracic, or sacral lesions develop

• **Fig. 59.13** Anencephaly. (A) Infant with anencephaly. (B) Ultrasonogram of a fetus with anencephaly. Note the absence of the normal cranial structures (arrows) superior to the orbits (O). (Courtesy of Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University, Portland, OR.)

hydrocephalus, in contrast to 90% of those with thoracolumbar, lumbar, or lumbosacral lesions (Lorber, 1961). Because of decompression caused by leakage of CSF from the MMC at birth, hydrocephalus and increased pressure may become evident only after surgical closure of the back (Stein and Schut, 1979).

Clinical management of the newborn with an NTD must be individualized. At present, surgical closure is advocated for most infants, resulting in decreased infection and improved cognitive abilities, ambulation, a lower prevalence of incontinence, and lower mortality (Hunt and Holmes, 1975; Stein et al., 1975; McLone, 1992). Usually, surgical management of the spinal defect occurs within 48 to 72 hours of birth. Involvement of a plastic surgeon should be considered, particularly with wide or complex lesions. CSF diversion may be needed concurrently or after the back has healed. Additional surgical procedures may be required for shunt malfunction or infection, sequelae of Chiari type II malformation (apnea, stridor, dysphagia), tethered cord, or syringohydromyelia. Initial evaluation of all neonates with a suspected NTD should include assessment of lower extremity sensory and motor function. Particular attention should be paid to spontaneous movements, response to touch and pain, and voiding and stooling pattern (particularly urinary retention and dribbling). Babies should be closely evaluated for other malformations, including congenital heart disease, unless they have been excluded by prenatal ultrasonography. Monitoring neonates for Chiari symptoms (apnea, stridor, poor feeding) and signs of increased intracranial pressure is also required. The overall approach should be multidisciplinary with involvement of the neurosurgery, urology, and physical therapy departments at a minimum. Long-term care of the child with MMC also requires symptom management for neurogenic bladder and bowel, as well as endocrine, orthopedic, rehabilitative, and neuropsychiatric care (reviewed in Apkon et al., 2014). Developmental pediatric, neurologic, or rehabilitation medicine specialists are often the primary point of contact for long-term management, depending on the resources available.

Fetal surgery has become an option for surgical repair of MMC. A randomized trial demonstrated that fetal surgery was associated with a lower rate of shunt placement and possibly better motor function at approximately 3 years of age but was also associated with premature delivery and maternal complications (Adzick et al., 2011; Grivell et al., 2014). In addition, mothers can require prolonged bedrest during the pregnancy and cannot deliver subsequent children vaginally. No improvements in neurogenic bowel/bladder have been observed as compared with those with standard postnatal care (Holmes et al., 2001), and the effects on long-term mobility, cognition, and other outcomes are under ongoing study. In light of these positive results, some centers promote fetal surgery as the standard of care; however, the American College of Obstetrics and Gynecology recommends an approach that balances the risks and benefits to both the fetus and the mother (ACOG, 2013).

Myeloschisis

Myeloschisis differs from MMC in that there is no CSF space beneath the neural placode that is against the anterior wall of the spinal cord; this defect also lacks overlying vertebrae and skin. This results in a continuous CSF leak. Depending on the anatomic level of the defect, neurologic deficits can include the lower extremities, bladder, and bowel. Closure may be more difficult than with MMC, and postclosure hydrocephalus may result (Jeelani and McComb, 2011). Like, MMC, this defect is initially diagnosed by elevated AFP level and by prenatal ultrasonography.

Skin-Covered Neural Tube Defects

Encephalocele

Encephalocele is considered a postneurulation disorder and likely occurs by mechanisms distinct from those for open NTDs (Copp et al., 2013). Encephaloceles typically present as cranial skull defects through which brain tissue protrudes. Less severe defects include cranium bifidum, where there is a failure of midline fusion of the skull, and cranial meningoceles that contain meningeal but not neural tissue. In up to 80% of patients, encephaloceles are occipital (Fig. 59.14), with the remainder in the parietal, frontonasal, intranasal, or nasopharyngeal regions. Geographic or ethnic-genetic factors influence the location of the lesion. Frontal encephaloceles are more prevalent in Southeast Asia, and occipital lesions are more common in Western populations (Mahapatra and Agrawal, 2006). A role for genetic factors is supported by a number of autosomal recessive syndromes associated with encephalocele (e.g., Meckel and Joubert syndromes; see earlier) (Brown and Sheridan-Pereira, 1992). Overall, about half of infants with encephaloceles have other major congenital anomalies, including microcephaly, arrhinencephaly, anophthalmia, cleft lip or palate, craniosynostosis, complex congenital heart disease, and other systemic abnormalities (Brown and Sheridan-Pereira, 1992).

Encephaloceles are also associated with various other CNS defects that influence surgical management and the severity of the outcome. In a series of 129 patients with anterior encephaloceles (including frontoethmoidal, orbital, transethmoidal, transellar, and interfrontal), 22 had associated hydrocephalus, and ACC was seen in 16 (Mahapatra, 2011). In addition to hydrocephalus, other anomalies include anomalous draining veins and nodular heterotopia (Diebler and Dulac, 1987; Menkes, 1991). The occurrence of lower occipital lobe encephalocele with skull base defects and malformations of the cerebellum and lower brainstem characterizes Chiari type III malformations.

Evaluation of the infant with an encephalocele can be aided by transillumination, skull radiographs, cranial ultrasonography, computed tomography scan, and MRI. Typically, MRI with magnetic resonance angiography and magnetic resonance venography is the study of choice, particularly for surgical planning. Frontonasal encephaloceles pulse or bulge with brief bilateral jugular vein compression, indicating communication with the subarachnoid space. Nasal gliomas, dermoids, and teratomas can all occur in the same region. Intranasal encephalocele should be suspected when an intranasal mass is found in a child with a broad nasal bridge and widely spaced eyes. Some of these children may also present with recurrent meningitis (Menkes, 1991). Basal encephaloceles are not usually diagnosed until childhood and can be located in the nasopharynx, sphenoid sinus, or posterior orbit.

In most patients, neurosurgical management is indicated early in life; however, large lesions or other severe CNS anomalies may preclude intervention, since typically, brain tissue exterior to the skull cannot be salvaged. Early treatment is imperative for those infants at high risk of meningitis caused by lesions that externally communicate and leak CSF. Surgical repair goals include dural closure and improving cosmesis. Complications can include postoperative CSF leakage or pseudomeningocele formation (Hervey-Jumper et al., 2011). For patients who are not surgical candidates, a palliative course should be pursued, although it can be quite challenging to decide which interventions are appropriate for a given patient. Ongoing discussions involving the family, subspecialists, and, ideally, dedicated palliative care providers are essential for provision of good care.

Encephaloceles can be associated with medically intractable seizures, which may be responsive to surgical resection (Faulkner et al., 2010). Survival and outcome remain difficult to predict because of the variability of presentation and surgical selection bias. One study of a series of children with encephaloceles reported overall mortality of 29% (45% in infants with posterior defects; 0% in infants with anterior defects) (Brown and Sheridan-Pereira, 1992). Neurologic deficits were severe in 33% of survivors. Mild neurologic deficits were found in 17% of survivors with anterior defects and in 50% of survivors with posterior defects. Intellectual disability prognosis depends on the amount of neural tissue within the defect (reviewed in Hervey-Jumper et al., 2011), and outcome can be quite favorable in patients with normal brain anatomy.

Meningocele

Meningocele is a skin-covered lesion containing meningeal tissue that has herniated through the posterior vertebral column (Copp and Greene, 2013). This occurs more commonly in the lumbosacral spine than in the cervical spine, and while the spinal cord does not extend into the defect, it may still be tethered and eventually

cause symptoms. Postnatally, meningoceles may be evaluated by spinal ultrasonography or MRI to evaluate the spine for tethering, syringohydromyelia, and diastematomyelia (Ladino Torres and DiPietro, 2014). At centers without extensive ultrasound expertise, MRI is the study of choice, and computed tomography is used mainly to delineate bony landmarks. Chiari type II malformation is not typically seen with posterior meningocele (Gupta et al., 2013).

Occult Spinal Dysraphisms

Occult spinal dysraphisms are closed defects of the distal part of the spinal cord with an intact dermal covering and are a result of defects of caudal neural tube formation (secondary neurulation). In some instances these defects are truly occult without any overlying abnormalities of the skin and may go undetected until they become symptomatic. Prenatally, they may be detected by fetal MRI (Schwartz and Rossi, 2015). In the vast majority of newborns, an occult spinal dysraphism is accompanied by cutaneous stigmata. Such lesions include abnormal hair tufts, hemangiomas, pigmented spots, skin tags, aplasia cutis congenita, cutaneous dimples or tracts

(particularly with CSF leak), or a subcutaneous mass, often apparent because of an asymmetric gluteal cleft (Hall et al., 1981; Albright et al., 1989; Scatliff et al., 1989). Sacral dimples or deep gluteal clefts between the buttocks without other features are rarely associated with spinal dysraphism, while dimples clearly above the gluteal cleft are associated with higher risk of spinal dysraphism.

Spinal dysraphisms are classified by a clinical, imaging, and developmental approach (Schwartz and Rossi, 2015). MRI is indicated for evaluation and diagnosis, when available. For closed dysraphisms, the initial distinction is based on the presence of a subcutaneous mass (Badve et al., 2011). Skin-covered lesions without a subcutaneous mass should be examined clinically for skin tags, evidence of spinal cord dysfunction, and anorectal malformations. Defects with subcutaneous masses are classified by the tissue types involved: lipomyelocele (fat and meninges), lipo-MMC (fat, nerve, and meninges), meningocele (meninges only), and terminal myelocystocele, which is a complex lesion with persistence of the terminal syringohydromyelic cavity (Schwartz and Rossi, 2015).

Other spinal cord lesions associated with occult dysraphism include diastematomyelia–diplomyelia, lipoma, teratoma, and other tumors, dermal sinus with or without dermoid or epidermoid cyst formation, and tethered cord (Menkes, 1991; Anderson and Brown, 2009). More severe lesions include neurenteric cysts, anterior meningocele, and caudal regression syndrome (dysraphia of sacrum and coccyx, atrophy of muscles and bones of the legs, fusion of spinal nerves and sensory ganglia, or agenesis of the distal part of the spinal cord) (Towfighi and Housman, 1991). As for other NTDs, infants of diabetic mothers are at increased risk of these lesions (Becerra et al., 1990). Abnormal conus and a thickened filum are usually present, and a symptomatic tethered cord is a common presentation after surgical repair of both skin-covered lesions and MMC (Bowman et al., 2009). Thickened filum with or without a small amount of fat can be seen frequently on spinal MRI and is usually not significant in the absence of a low-lying conus and neurologic symptoms.

Clinical Features and Diagnosis

Progressive functional impairment can occur as the cord is stretched against the fixed filum (Lew and Kothbauer, 2007), with neurologic impairment rarely presenting in the newborn period (Hertzler et al., 2010). Atypical voiding and stooling (particularly continuous dribbling) should prompt bladder volume measurement and urology and neurosurgical referrals. Delay in walking, disturbed sphincter control, contractures of the feet or legs, and pain in the back or legs may present in infancy or childhood, while gait and sphincter abnormalities, foot deformities, and scoliosis are more common in older patients. Rarely, recurrent meningitis and acute loss of function are seen.

Because prophylactic surgical intervention may prevent deterioration, early diagnosis is a necessity (Gower et al., 1988; Scatliff

et al., 1989; Hertzler et al., 2010). In neonates this evaluation may be facilitated by spinal ultrasonography, which permits a dynamic evaluation of lower spinal cord mobility, and MRI to define structural anomalies of the cord. Evaluation should occur as soon as a closed spinal dysraphism is suspected. The timing of surgical management depends on the presence or progression of neurologic symptoms and signs. The care of these children requires a multidisciplinary approach for management of neurosurgical issues and comorbidities (Cornette et al., 1998).

Brain Injury in the Preterm Infant

STEPHEN A. BACK AND STEVEN P. MILLER

KEY POINTS

- Intraventricular hemorrhage (IVH) remains a common cause of chronic neurologic morbidity. Despite a gradual decline in the incidence of most grades of IVH, the increased survival of very low birth weight infants has resulted in an increase in the absolute number of infants with IVH.
- Preterm infants are currently at much lower risk of severe white matter injury (WMI) that typically results in focal cystic necrosis and secondary gray matter degeneration. Cystic WMI is commonly associated with cerebral palsy, cortical visual impairment, and a spectrum of cognitive and learning disabilities.
- Most preterm infants commonly display less severe diffuse WMI that results primarily in myelination disturbances related to death of oligodendrocyte progenitors (preOLs). Both cranial ultrasonography and magnetic resonance imaging (MRI) appear to underdiagnose the extent of diffuse WMI.
- Chronic diffuse WMI results in reduced cerebral white matter growth related to a series of dysmaturation events that result in regeneration of preOLs that fail to differentiate to myelinating oligodendrocytes. Chronic diffuse WMI is also accompanied by reduced cerebral gray matter growth that appears to be related to widespread disturbances in neuronal maturation rather than loss of developing neurons.
- Diffuse WMI, often reflected in punctate WMI on diagnostic MRI, is linked to a broad spectrum of persistent neurobehavioral disabilities that include impairments in motor and cognitive skills. Punctate WMI is most readily diagnosed on early-preterm MRI scans. The burden of punctate WMI (lesion volume and location) predicts motor and cognitive dysfunction. The spectrum of neurodevelopmental impairments that follow WMI in the preterm neonate are consistent with the dysmaturation described in white matter and cerebral gray matter.
- These recently recognized forms of cerebral gray and white matter dysmaturation present new challenges for diagnosis and suggest new therapeutic strategies to promote reversal of the processes that cause dysmaturation of neurons and preOLs.

General Principles of Preterm Brain Injury

The preterm brain is susceptible to a broad spectrum of injury that ranges from diffuse nonnecrotic lesions to hemorrhage to severe necrotic tissue destruction. Brain injury is initiated by two major *upstream mechanisms*, *ischemia* and *infection/inflammation*, that may interact and potentiate each other. Because the developing

brain is rapidly evolving, the susceptibility to injury is critically related to the timing and severity of the insult. As brain development progresses, distinct populations of cells are selectively more vulnerable to injury, whereas others display greater resistance. Patterns of cell vulnerability shift as the brain matures. Moreover, a wide variety of additional factors may sensitize the brain's susceptibility to injury. The preterm brain may be exposed to a variety of subclinical factors that in isolation may not be injurious but in combination may synergize to potentiate injury. Such factors include nutritional status, systemic illnesses, exposure to glucocorticoids, sedatives, or drugs of abuse, the burden of painful procedures, and other sources of neonatal stress. Equally important to consider is the concept of tolerance in which an antecedent subinjurious insult may reduce the severity of a subsequent one. For example, a low-grade fetal infection may be protective against a subsequent more severe hypoxic-ischemic insult.

This chapter addresses three common and frequently overlapping forms of preterm cerebral injury: intraventricular hemorrhage (IVH), white matter injury (WMI), and gray matter injury. The impact of preterm cerebral injury is considerable. Among children born very preterm, even with modern neonatal intensive care, 5%–10% have major motor deficits, including cerebral palsy related to significant WMI, and more than half have significant cognitive, behavioral, or sensory deficits (Vohr, 2014). These cognitive and neurobehavioral deficits are increasingly observed in the absence of significant motor impairments or cerebral palsy (Gonzalez and Miller, 2006), which has also suggested *primary* involvement of multiple gray matter structures. Gray matter injury was previously attributed to cystic necrotic WMI that led to *secondary* cortical and subcortical gray matter degeneration. Although contemporary cohorts of preterm survivors commonly display less severe injury, these milder forms of injury are associated with both reduced cerebral gray matter growth and reduced cerebral white matter growth. The impairment in cerebral growth arises from complex and disparate responses of neurons and glia that fail to fully mature during a critical window in development of neural circuitry. These observations support the notion that much of the spectrum of motor and neurobehavioral disabilities currently seen in preterm survivors is related to cerebral maturational disturbances rather than overt injury (Back and Miller, 2014). Thus preterm children with a broadly normal intelligence quotient currently display motor dyspraxia (Miller et al., 2000; Sanger et al., 2006), processing deficits in attention and executive functions (e.g., cognitive flexibility,

inhibitory control, working memory) (Anderson and Doyle, 2004; Marlow et al., 2005; Diamond et al., 2007), and visually based challenges with information processing and language (Grunau et al., 1990; Whitfield et al., 1997; Grunau et al., 2002; Taylor et al., 2004; Saavalainen et al., 2007; Luu et al., 2009). These cognitive and behavior problems persist to young adulthood (Curtis et al., 2002; Hack et al., 2002; Grunau et al., 2004; Taylor et al., 2004; Lindstrom et al., 2007; Nosarti et al., 2007; Saavalainen et al., 2007). Hence these highly prevalent neurocognitive impairments support widely distributed disturbances in brain growth and connectivity that involve both gray matter and white matter (Doesburg et al., 2011).

Intraventricular and Periventricular Hemorrhage in the Preterm Infant

Pathogenesis

IVH is a common injury in the preterm brain, originating in the subependymal germinal matrix (Ballabh, 2010). Cortical neuronal and glial cell precursors develop from the germinal matrix and adjacent ventricular germinal zone during the late second and early third trimesters. The subependymal germinal matrix is a highly vascularized region whose arterial supply is derived from the anterior and middle cerebral arteries as well as the anterior choroidal artery. These arteries feed an elaborate capillary network of thin-walled vessels that is continuous with a deep venous system that terminates in the vein of Galen. The terminal, choroidal, and thalamostriate veins course anteriorly to form the internal cerebral vein, which courses posteriorly to join the vein of Galen, thus leading to a U-shaped turn in the direction of blood flow. Involution of the germinal matrix occurs with advancing gestation.

The predisposition of the preterm infant to IVH is due to several factors. A pressure-passive state exists because of the lack of autoregulation of blood flow in the cerebral arterioles of the preterm brain. In the presence of a highly vascularized subependymal germinal matrix, the risk of IVH is enhanced by the lack of a supporting basement membrane for the matrix blood vessels, an increased amount of matrix fibrinolytic activity, and a decrease in extravascular tissue pressure in the first few days of extrauterine life. Thus IVH may occur in the setting of elevated venous pressure or an increase in fluctuations in cerebral blood flow (CBF) velocity triggered by factors that include respiratory distress, pneumothorax, asphyxia, myocardial failure, patent ductus arteriosus, hypotension, hypothermia, and hyperosmolality (Ment and Schneider, 1993). Fluctuating pressure passivity is common in preterm infants and may be associated with IVH (Soul et al., 2007; O'Leary et al., 2009).

IVH has been produced experimentally after hypotension followed by reperfusion (Goddard-Finegold et al., 1982; Ment et al., 1982). These studies support the observation that IVH is more likely when an early period of prolonged hypotension is followed by an increase in blood pressure (Miall-Allen and Whitelaw, 1987; Miall-Allen et al., 1987). Isolated hypertension associated with seizures, intubation, and suctioning also predisposes the brain to IVH. Even gavage feeding and surfactant administration can lead to changes in cerebral hemodynamics, as measured by near-infrared spectroscopy, that lead to IVH (Roll et al., 2000; Baserga et al., 2003; Kaiser et al., 2004). **Box 60.1** lists key factors that may interact to produce IVH.

• BOX 60.1 Pathogenic Factors Leading to Intraventricular Hemorrhage

Increase in cerebral blood flow
Fluctuation in cerebral blood flow
Increase in cerebral venous pressure
Endothelial injury
Vulnerable germinal matrix capillaries
Coagulation disturbances
Increased fibrinolysis

Cellular injury in infants with grade III or grade IV (periventricular hemorrhagic infarction; PVHI) IVH may occur from antecedent ischemic injury, a decrease in cerebral blood flow, increased intracranial pressure, or vasospasm. More severe IVH is associated with cerebral WMI, cerebellar injury (see later), and less frequently pontine neuronal necrosis (Volpe, 2008). In this setting, venous infarction leads to neuronal death as well as glial death. Posthemorrhagic hydrocephalus (PHH) is a common sequela of severe IVH and of PVHI. The optimal treatment of PHH to promote optimal neurodevelopmental outcomes remains controversial, with recent data favoring earlier intervention (de Vries et al., 2002; Srinivasakumar et al., 2013).

Site, Incidence, and Timing of Hemorrhage

In preterm infants, germinal matrix hemorrhage is most commonly seen at the junction of the terminal, choroidal, and thalamostriate veins in the germinal matrix overlying the body of the caudate nucleus at the level of the foramen of Monro. Parenchymal hemorrhage occurs most commonly in the frontoparietal region, in approximately 15% of cases, where it appears not to be an extension of the IVH but rather a separate process—a hemorrhagic infarction. The hemorrhage is more often unilateral or, in less than 30% of cases, asymmetrically bilateral.

The incidence and severity of IVH increase with decreasing gestation. IVH occurs in only approximately 5% of term newborns. IVH previously occurred in 40%–60% of very low birth weight (VLBW) infants (less than 1500 g birth weight). An overall reduction in the incidence of IVH in VLBW infants from 15% to 25% has occurred in the past 2 decades (Paneth et al., 1993; Vohr et al., 2000; McCrea and Ment, 2008), yet the rate of PVHI appears stable (Hamrick et al., 2004b). The rates of grade III IVH and PVHI remain at 16% in VLBW infants (Stoll et al., 2010). As these smaller infants are surviving in higher numbers, severe IVH and PVHI still contribute importantly to poor neurodevelopmental outcomes.

Although there has been a gradual decline in the incidence of most grades of IVH, the increased survival of VLBW infants has resulted in an increase in the absolute number of infants with IVH.

The risk period for the occurrence of IVH is highest in the first 3 or 4 days of life. Hemorrhage is rarely seen at birth, although it has been reported as early as the first hour of life (Ment et al., 1984). Prenatal hemorrhages can occur, especially in the setting of neonatal alloimmune thrombocytopenia. Twenty-five percent of hemorrhages occur by the sixth hour of life, and 50% of hemorrhages occur during the first 24 hours of life. Less than 5% of newborns develop IVH after the fourth or fifth day of life (Ment and Schneider, 1993). Extension of the hemorrhage may occur

during the first few days because of disturbances in cerebral blood flow.

Clinical Presentation

The clinical presentation of IVH in the newborn depends on the extent of the hemorrhage. It may range from *asymptomatic* to a sudden and catastrophic deterioration that manifests itself with neurologic signs such as stupor or coma, seizures, decerebrate posturing, or apnea. A tense fontanel together with a sudden drop in hematocrit, hyperglycemia, hyperkalemia, hypotension, or bradycardia may herald an IVH. Inappropriate secretion of antidiuretic hormone may occur. The more common presentation, however, is that of a gradual clinical deterioration with an altered level of consciousness, hypotonia, abnormal extremity, or eye movements. In 25%–50% of cases, clinical signs are lacking (Dubowitz et al., 1998).

Grading of Intraventricular Hemorrhage

Ultrasound examination is a reliable and sensitive bedside technique for evaluation of the severity of IVH in the newborn nursery. Papile et al. (1978) adapted the standard grading system originally applied to computed tomographic images of IVH to ultrasound images. They classified IVH into four grades of severity related to the location and extent of the hemorrhage (Fig. 60.1, Table 60.1). This classification system was previously used widely for outcome studies. Currently, the more widely used grading system is that proposed by Volpe (2008), which relies on the cranial ultrasound examination to define the extent of ventricular hemorrhage. Because parenchymal involvement is a distinct process, it is not included in the continuous grading of IVH severity (Table 60.1). PVHI appears to arise from venous infarction of the periventricular white matter rather than from a direct extension of the IVH into the parenchyma (Volpe, 2008). Hence the presence of intracerebral hemorrhage or parenchymal lesions is described separately and is not designated as grade IV. Intraparenchymal hemorrhage is followed in 1 to 8 weeks by tissue destruction and formation of a porencephalic cyst. Serial ultrasound examinations are especially important in linking the severity of IVH with neurodevelopmental outcomes (Rademaker et al., 2005).

In addition to various forms of cerebral WMI, IVH may cause graded injury to the cerebellum (Fig. 60.2) that manifests itself as magnetic resonance imaging (MRI) defined changes in microstructure (Tam et al., 2009) and reductions in cerebellar growth

(Tam et al., 2011b). This reduced growth appears to be related to a large population of proliferative external granule cells that are the precursors that generate the internal granule cell layer, which accounts for most of the cells in the human brain. These cerebellar progenitors may be particularly vulnerable to the toxicity of IVH-derived blood products, which are detected by MRI as hemosiderin deposition on the surface of the brainstem and cerebellum (Volpe, 2009). The heightened vulnerability of cerebellar progenitors is consistent with serial neuroimaging studies of human preterm survivors that demonstrated disrupted cerebellar growth in response to postnatal glucocorticoid exposure (Tam et al., 2011a).

Outcome and Prognosis

Isolated grade I and II hemorrhages generally resolve without evolution. Grade III hemorrhages evolve over a period of 1 to 3

• **Fig. 60.1** The Progressive Grades of Intraventricular Hemorrhage from Mildest to Most Severe. (A) Grade I hemorrhage involves less than 10% of the ventricular volume of the lateral ventricles. (B) Grade II involves 10%–50% of the ventricular volume. (C) Grade III involves more than 50% of the ventricular volume and is frequently associated with ventricular dilatation. (D) Hemorrhage is associated with parenchymal infarction.

TABLE 60.1

Grading of Intraventricular Hemorrhage by Cranial Ultrasound Examination Findings

| Papile Grading System | | Volpe Grading System ^a | |
|-----------------------|--|-----------------------------------|---|
| I | Subependymal hemorrhage with minimal or no IVH | I | Germinal matrix hemorrhage <10% IVH |
| II | Definite IVH without distention of the ventricles | II | IVH 10%–50% |
| III | Enlargement of the ventricles secondary to distention with blood | III | IVH >50%, usually with distention of lateral ventricle |
| IV | Extension of the hemorrhage into the parenchyma along with IVH and enlargement | Separate notation | Periventricular echodensity signifying parenchymal lesion |

^aBy cranial ultrasound examination.
IVH, Intraventricular hemorrhage.

• **Fig. 60.2** Intraventricular Hemorrhage Is Associated With Impaired Growth of the Cerebellum. (A, B) The normal appearance of the brain and cerebellum in a preterm neonate born at 28 weeks' gestational age who was imaged by magnetic resonance imaging (MRI) at 30.3 weeks. (C, D) Smaller cerebellum (arrowhead) associated with intraventricular hemorrhage (IVH) (arrow) in a preterm neonate born at 28 weeks' gestational age who was imaged by MRI at 30.1 weeks.

weeks and may produce a fibrotic reaction that obliterates the subarachnoid space with subsequent ventricular dilatation and hydrocephalus. Clinical symptoms of progressive hydrocephalus, such as rapid head growth, a full anterior fontanel, or separation of cranial sutures, often appear days or weeks after the onset of ventricular dilatation. The delayed onset of clinical symptoms is related to the presence of a large subarachnoid space as well as the paucity of myelin in premature infants.

Outcomes differ between studies, but in general, mortality rates are not significantly increased in infants with a grade I or grade

II hemorrhage. In VLBW infants, 10%–15% sustain more severe hemorrhages (McCrea and Ment, 2008). These grade III or grade IV hemorrhages are associated with increased mortality. In 15% of cases of IVH, areas of PVHI occur that are associated with mortality rates that approach 50% greater than those in infants without IVH (Brouwer et al., 2008; Sarkar et al., 2009; Bolisetty et al., 2014).

Several studies have focused on the relationship between IVH and subsequent neurodevelopmental outcomes. In extremely low birth weight (ELBW) survivors, even grade I and grade II IVH

have been associated with a modest increase in morbidity relative to those infants without IVH in some studies (Patra et al., 2006; Vavasseur et al., 2007; Klebermass-Schrehof et al., 2012) but not all studies (Payne et al., 2013). Given the considerable morbidity associated with extreme prematurity, it can be challenging to independently assess the increased risk of neurologic complications associated with lower grades of IVH. One more recent study of nearly 1500 ELBW survivors found that grade I and grade II IVH were associated with a 7% greater rate of poor neurodevelopmental outcomes after exclusion of other cranial ultrasound abnormalities such as WMI or porencephaly (Bolisetty et al., 2014). The prognosis for infants with grade I and grade II IVH thus may not be benign if there is comorbid brain injury. This increased risk of abnormal outcome may be related to underrecognized WMI or gray matter injury (Inder et al., 1999; O'Shea et al., 2012). Follow-up studies have shown that the degree of IVH at birth and the presence of ventriculomegaly are predictors of neurologic status at a corrected age of 24 months. Neurologic sequelae occur in up to 35% of infants with grade III IVH and 55% with grade IV IVH (Brouwer et al., 2008). In a longitudinal study of preterm infants with a birth weight less than 1750 g, only infants with grade III or grade IV IVH differed in neurologic examination findings from term control infants at 2 years of age (Vohr et al., 2000). Unlike motor function, cognitive function as assessed by the Bayley scores deteriorated in the first 18 months of life. The persistence of ventriculomegaly in grade III or grade IV IVH is associated with greater risk of more severe neurologic sequelae that include seizures, cerebral palsy, and severe impairment of vision or hearing (Ancel et al., 2006). The presence of hydrocephalus with or without shunting at term increases the risk of a poor neurodevelopmental outcome (Radic et al., 2015). Adverse outcomes are significantly worse for ELBW infants with PHH that required a shunt, highlighting the importance of appropriate and timely intervention (Adams-Chapman et al., 2008).

Prevention

Prevention of preterm birth is the most effective method of reducing the incidence of IVH. In the event of preterm labor, it is advisable that the neonate be born at a center specializing in high-risk deliveries. The risk of IVH is higher in neonates who are outborn and transported after birth. Prenatal administration of steroids is associated with a decreased risk of IVH and cerebral palsy (Roberts and Dalziel, 2006), but prenatal administration of magnesium sulfate does not reduce the rates of IVH (Canterino et al., 1999; Rouse et al., 2008). Optimal neurologic intensive care of the preterm infant includes reduced exposure to hyperventilation, hypocarbia, or hypoxia, as well as maintenance of adequate mean arterial pressure (MAP). Abrupt elevations in CBF may be precipitated by excessive handling or tracheal suctioning. Other risks for IVH include pneumothorax, acidosis, rapid infusions of sodium bicarbonate, and volume expanders.

Because of the increased risk of neurodevelopmental sequelae in infants with IVH, several clinical trials have been performed to evaluate the role of prolonged neuromuscular paralysis in preterm infants. A metaanalysis of five trials concluded that although neuromuscular paralysis with pancuronium may help decrease the risk of IVH and pneumothorax in asynchronously breathing infants, its routine use was not recommended because of concerns about safety and long-term pulmonary and neurologic effects (Cools and Offringa, 2000).

A low MAP or increased fluctuations of blood pressure have been associated with an increased risk of IVH (Perlman and Volpe, 1982). Although close monitoring of the MAP is recommended, there is no evidence that pharmacologic manipulation of systemic blood pressure (e.g., with pressors, steroids, or volume expanders) to achieve a set goal (e.g., MAP >30 mmHg) alters the incidence of IVH or improves neonatal outcome. In early studies, phenobarbital administration appeared to be beneficial by preventing fluctuations in blood pressure (Donn et al., 1981; Arroyo-Cabrales et al., 1998). However, a subsequent multicenter trial of prenatal administration of phenobarbital (10 mg/kg) to 110 women provided no reduction in the postnatal frequency of IVH in preterm infants between 24 and 33 weeks' gestational age (Kaempf et al., 1990). A larger trial confirmed these findings, and long-term follow-up at 18 to 22 months found no difference in neurodevelopmental outcomes (Shankaran et al., 1997, 2002). A metaanalysis of 10 trials of postnatal administration of phenobarbital showed no difference in the rates of severe IVH or ventriculomegaly (Whitelaw and Odd, 2007). Therefore postnatal administration of phenobarbital does not appear to be beneficial for prevention of IVH.

Pharmacologic doses of vitamin E, an antioxidant, were associated with a reduction in the incidence of IVH in low birth weight infants when given intramuscularly (Speer et al., 1984). However, after reports of the association of such large doses of vitamin E with sepsis and necrotizing enterocolitis, its use for prevention of IVH was curtailed (Finer et al., 1984; Johnson et al., 1985).

Indomethacin, a prostaglandin synthase inhibitor, was originally found to decrease the incidence of IVH in infants weighing less than 1250 g (Ment et al., 1985). However, later studies, on the long-term effects of indomethacin prophylaxis in these ELBW infants, showed no increase in the rate of survival without neurosensory impairment, despite a reduction in the rate of severe IVH (Schmidt et al., 2001; Vohr et al., 2003). A metaanalysis of 19 trials and 2872 infants found an increased risk of oliguria, which was, however, not associated with major renal impairment. There was no difference in the incidence of necrotizing enterocolitis, a modest reduction in the number of infants with severe IVH and no difference in long-term neurosensory impairments (Fowlie and Davis, 2002). Prenatal administration of indomethacin, as a tocolytic to arrest preterm labor, is associated with increased risks of severe IVH and WMI (Hammers et al., 2015). Yet, recent evidence suggests decreased risk of WMI with prolonged postnatal indomethacin exposure in the preterm neonate (Miller et al., 2006; Gano et al., 2015).

Prenatal administration of steroids (Elimian et al., 2000; Smith et al., 2000; Canterino et al., 2001; Eriksson et al., 2009; Abbasi et al., 2010; Wong et al., 2014) and surfactant replacement therapy (Soll and Dargaville, 2000; Kribs et al., 2015) decrease the incidence of IVH as well as neonatal mortality in low birth weight infants. However, an increase in the incidence of IVH may occur with surfactant administration as a result of the mode of instillation (Cowan et al., 1991; Hellstrom-Westas et al., 1991, 1992) and the drop in PaCO₂ with improved ventilation. Since a significant drop in MAP and CBF volume can occur during surfactant administration, attention should be paid to the speed and volume of instillation.

Mechanical ventilation may be associated with an increased risk of IVH (Cools et al., 2015). Several studies evaluated the early use of high-frequency ventilation versus conventional ventilation for infants with respiratory distress syndrome. These studies found either an increased risk of IVH with high-frequency oscillatory ventilation (HIFI Study Group, 1989; Cools and Offringa, 1999;

Moriette et al., 2001) or no increase in the risk of IVH (Clark et al., 1996; Keszler et al., 1997). The results of a recent metaanalysis of 19 studies and 4096 infants found no increased risk of severe IVH or WMI in preterm infants treated with high-frequency versus conventional ventilation (Cools et al., 2015).

It is important to avoid both hypocarbia ($\text{PCO}_2 < 30$ mmHg) and hypercarbia ($\text{PCO}_2 > 55$ mmHg) because of their significant effects on CBF (Young and Yagel, 1984; Gleason et al., 1989; Pryds et al., 1989, 1990; Habgood et al., 1991; Pryds, 1991). Avoiding low PCO_2 has been shown to be neuroprotective in animal studies (Sola et al., 1983; Vannucci et al., 1995). Hypocarbia is associated with hypotension and an increased risk of IVH and WMI (Erickson et al., 2002; Fabres et al., 2007). Hypercarbia promotes increased cerebral blood flow, which in the presence of other therapies aimed at increasing blood pressure increases the risk of IVH (Fabres et al., 2007; Vela-Huerta et al., 2009; Ambalavanan et al., 2015).

Free radicals and iron have been shown to be damaging to oligodendrocyte progenitors (preOLs) in both cell culture and animal studies (Back et al., 1998; Dommergues et al., 1998), and iron-chelating agents such as deferoxamine have been shown to be neuroprotective in animal models (Sarco et al., 2000). However, clinical studies are lacking to evaluate the benefit of antioxidants in the setting of posthemorrhagic infarction. As 80% of iron transfer occurs in the third trimester, it is also important to emphasize that iron sufficiency is required for normal brain development, and so withholding iron administration may be detrimental.

Management

Because of the high risk of IVH and ischemic WMI in the early perinatal period, short-term management should be focused on elimination of factors shown to promote excessive fluctuations in CBF (Perlman and Volpe, 1982) and the prevention of nosocomial infections (Chau et al., 2012). Clinical practices to limit fluctuations in CBF include maintenance of blood gases and metabolic status within a normal range, avoidance of excessive suctioning and handling, and detection and treatment of seizures. Systemic blood pressure should be maintained with particular attention to the rate of administration of fluids. Infants with birth weights of less than 1500 g or a gestational age of less than 32 weeks should undergo a screening ultrasound examination to detect IVH.

Serial cranial ultrasound examinations remain the optimal diagnostic modality to screen neonates for IVH and WMI at the bedside in the perinatal period, when the risk of IVH is the highest (Benders et al., 2014). An ultrasound scan on the fourth postnatal day detects 90% of lesions (de Vries et al., 2004). Because extension of a hemorrhage may occur during the next several days, a repeated ultrasound examination after 5 days is necessary to establish the extent of the IVH. Serial imaging is often necessary, because about half of infants with ventricular enlargement from IVH develop rapidly progressive ventricular dilatation during the next 4 to 8 weeks. In the setting of severe IVH, regular screening ultrasound examinations to reevaluate the neonate for slowly progressive hydrocephalus should complement measurement of head circumference, examination of the fontanel, and assessment of clinical status in the first 4 weeks of life. The decision to continue intensive care support is partly informed by the severity of the IVH and associated brain injury as assessed by a combination of cranial ultrasound and MRI examinations. MRI is the optimal imaging modality to detect smaller cerebellar hemorrhages and potentially more subtle forms of noncystic WMI (de Vries et al., 1998; Inder et al., 2003a; Miller et al., 2003).

Evidence-based guidelines are still mostly lacking for the optimal clinical management of posthemorrhagic hydrocephalus. Serial lumbar punctures or ventricular taps were previously used in the nonsurgical management of PHH to temporarily prevent progression of hydrocephalus and potentially reduce the need for shunt placement. Systematic review of four controlled trials found that the early removal of debris from liquefied blood clots did not reduce mortality, developmental disabilities, or the risk of permanent shunt dependence and was associated with an increased risk of central nervous system (CNS) infection (Whitelaw, 2001; Mazzola et al., 2014). However, more recent studies suggest that increasing ventricular size predicts more adverse neurodevelopmental outcomes and that earlier intervention with lumbar punctures and/or reservoirs may reduce the eventual need for ventriculoperitoneal (VP) shunts (de Vries et al., 2002; Srinivasakumar et al., 2013).

A randomized controlled trial of the combined use of furosemide and acetazolamide in 177 infants with PHH was also ineffective in reducing VP shunt placement and was associated with an increased risk of adverse neurologic outcomes (Kennedy et al., 2001). Several studies also found no benefit of early intraventricular delivery of a fibrinolytic agent (tissue plasminogen activator, urokinase, or streptokinase) to reduce complications associated with PHH (Whitelaw, 2000; Mazzola et al., 2014). In a multicenter randomized clinical trial of drainage, irrigation, and fibrinolytic therapy (DRIFT) when compared with removal of excess cerebrospinal fluid (CSF) via a reservoir, DRIFT reduced severe cognitive disability in survivors and overall death or severe disability, despite an increase in secondary intraventricular bleeding (Whitelaw et al., 2010).

Early placement of a VP shunt that diverts cerebrospinal fluid from the lateral ventricles to the peritoneal cavity in a premature infant weighing less than 2.5 kg is problematic because of the risk of skin breakdown, shunt obstruction, and infection. Placement of a ventricular access device (e.g., Ommaya/Rickham reservoir), an external ventricular drain, or a ventriculosubgaleal shunt is a temporary measure for the early management of PHH. A small retrospective historical cohort study found that ventriculosubgaleal shunts compared with ventricular access devices may reduce the need for daily CSF aspiration (Lam and Heilman, 2009). However, both approaches had similar complication rates, and similar numbers of infants ultimately required VP shunt placement (Limbrick et al., 2010). Either placement of VP shunts or endoscopic third ventriculostomy is a long-term treatment option for PHH, and both have similar clinical outcomes (Limbrick et al., 2014).

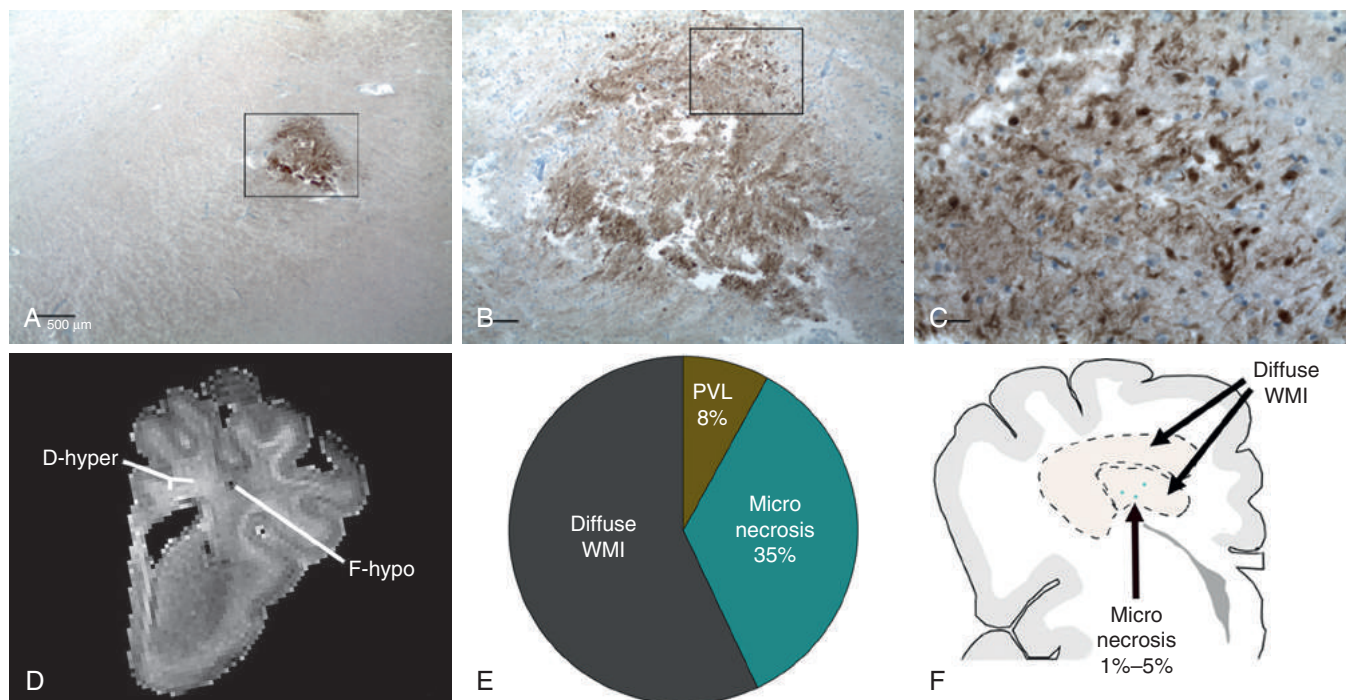

White Matter Injury

Spectrum of Human White Matter Injury

The spectrum of human WMI includes three major identifiable forms of disease: focal cystic necrosis, focal microscopic necrosis, and diffuse nonnecrotic lesions. Large cystic necrotic lesions greater than about 1 mm in diameter are the most severe, but their incidence has decreased markedly in recent years (Fig. 60.3). In several series, focal cystic lesions were detected by MRI in less than 5% of cases (Maalouf et al., 2001; Counsell et al., 2003; Inder et al., 2003a; Miller et al., 2003; Hamrick et al., 2004a; Groenendaal et al., 2010). In fact, the incidence of all forms of necrotic WMI were found to have decreased by approximately 10-fold in contemporary cohorts relative to retrospective cases from earlier decades (Buser et al., 2012). Although the incidence of large necrotic lesions has decreased markedly, discrete small foci of microscopic necrosis

• **Fig. 60.3** Severe White Matter Injury Results in Focal or Diffuse Tissue Destruction (Periventricular Leukomalacia). (A) This autopsy brain, from an infant who died of complications of prematurity, shows large foci of severe cystic necrosis (*arrowheads*) in frontal (*upper specimen*) and parietal (*lower specimens*) periventricular white matter. (B) Histologic analysis of the frontal lesion (stained with hematoxylin and eosin) shows a large focus of necrosis (*arrowheads*) adjacent to the lateral ventricle. The *inset* shows a high-power detail of the edge of the lesion (*arrows*), where marked rarefaction of the tissue can be appreciated adjacent to a region of gliosis at the *lower left*. (C) Appearance of cystic necrotic white matter injury on magnetic resonance imaging. Images from a preterm infant born at 33 weeks' gestational age and scanned at 5 weeks of age (38 weeks' adjusted gestational age). Small areas of cavitation (*arrowheads*) are appreciated as hypointensity on the sagittal T1-weighted image and as hyperintensity on the axial T2-weighted image (D). • **Fig. 60.4** Microscopic Necrosis Occurs Commonly but Constitutes a Small Fraction of the Total Burden of Preterm Cerebral White Matter Injury. (A–C) Typical sparse distribution of microcysts visualized with a marker of degenerating axons in a human autopsy brain at 32 weeks' postconceptional age. (B, C) Higher-power detail of the degenerating axons in the microcyst seen in the box in (A). (D) A microcyst visualized by high-field (12 Tesla) ex vivo magnetic resonance imaging as a focal hypointense lesion (F-hypo) on T2. This lesion was detected 2 weeks after global cerebral ischemia in a fetal sheep model of preterm white matter injury (WMI) (Riddle et al., 2011). Note the surrounding diffuse WMI, which is seen as a diffuse hyperintense signal (D-hyper). (E) Pie chart showing the relative percentages of human diffuse WMI, cystic periventricular leukomalacia (PVL), and microscopic necrosis. Note that microcysts often overlap in distribution with regions of diffuse WMI. (F) The relative burden of human microcysts (blue dots) compared to diffuse WMI (tan shading), which typically constitutes more than 80% of the total burden of WMI. Scale bars: (A) 500 μm; (B) 100 μm; (C) 25 μm. (From Back SA, Miller SP. Brain injury in premature neonates: a primary cerebral dysmaturation disorder? *Ann Neurol*. 2014;75:469–486.)

(microcysts) less than 1 mm in diameter appear to be much more common (Pierson et al., 2007). Similarly to cystic necrosis, microcysts are destructive lesions enriched in cellular debris, degenerating axons, and phagocytic macrophages (Fig. 60.4A–C). Because of their small size, microcysts are typically not detected on clinical MRI scans at field strengths of 3 Tesla (T) but can be detected experimentally at higher magnetic field strengths of 12 T (Riddle et al., 2011; see Fig. 60.4D). In a study of human archival and contemporary autopsy cases, microcysts were observed in at least 30% of cases, but they constituted approximately 1%–5% of the total burden of WMI (Buser et al., 2012). Hence although microscopic necrosis occurs with high incidence, the burden is typically low (see Fig. 60.4E–F). It should nevertheless be emphasized that the clinical significance of these small necrotic lesions remains an important but clinically inaccessible question, since microcysts are not readily detected by clinical MRI. It is thus possible that microcysts may be clinically silent or a significant contributor to motor or cognitive disabilities, depending on the extent to which they localize to functionally important regions of white matter.

Diffuse WMI is the most frequently observed form of injury in contemporary cohorts of preterm newborns (Buser et al., 2012). Diffuse WMI is much more widely distributed than previously appreciated and comprises activated astrocytes and microglia that

extend widely beyond the foci of necrosis (see Fig. 60.4E–F). In contrast to necrotic injury, diffuse WMI is defined by selective degeneration of late preOLs, whereas axons are mostly spared except in necrotic foci (Haynes et al., 2008; Riddle et al., 2012). Human preOLs are the precursors of all the myelinating cells of the CNS and are particularly susceptible to significant oxidative damage of a magnitude seen with hypoxia–ischemia (HI) in the clinical context (Back et al., 2005b). The susceptibility to preterm WMI peaks at approximately 23 to 32 weeks' postconceptional age and coincides with a developmental window when preOLs predominate in human cerebral white matter. Paradoxically, it was shown experimentally that ischemia is necessary but not sufficient to cause WMI. Even under conditions of moderately severe ischemia, some regions of white matter may be relatively spared. The regions of particular vulnerability to WMI are defined by both the timing of the appearance and the distribution of susceptible preOLs (Riddle et al., 2006).

Although cranial ultrasound examination is the preferred bedside imaging technique for diagnosing necrotic WMI, it has limited sensitivity for diagnosing diffuse WMI (Maalouf et al., 2001; Inder et al., 2003a; Miller et al., 2003). MRI is the preferred method to visualize diffuse WMI (Fig. 60.5A–C). On diagnostic MRI scans, WMI is visualized as either discrete focal areas or more diffuse areas of magnetic resonance signal abnormalities (Chau

• **Fig. 60.5** Diagnostic and Experimental Magnetic Resonance Imaging Approaches to Define Dysmaturation Processes Related to Diffuse White Matter Injury. (A) Diffuse human white matter injury (WMI) on diagnostic magnetic resonance imaging (MRI) (1.5 Tesla (T); T1) has the appearance of bilateral multifocal signal hyperintensities (*arrows*). (B) Diffusion tensor imaging defines the microstructure of white matter tracts and can be used to follow the long-term progression of diffuse WMI. (C) Magnetic resonance spectroscopic imaging can be applied to define biochemical and metabolic abnormalities associated with diffuse WMI. Both diffusion tensor imaging and magnetic resonance spectroscopic imaging detect abnormalities beyond the areas of signal abnormality on T1-weighted images. (D) Diffuse WMI defined by high-field ex vivo MRI at 12 T in a preterm fetal sheep model of global cerebral ischemia. Diffuse WMI was visualized as extensive hypointense regions (*D-hypo*) on a T2-weighted image at 1 week after ischemia. (E) The typical histopathologic features of diffuse WMI seen on MRI. Note the pronounced staining of reactive astrocytes (*green*) and microglia/macrophages (*red* and *inset*) indicative of a diffuse inflammatory response quantified in (F); the *asterisks* indicate $P < .05$. Scale bar in (E) 100 μ m. GFAP, Glial fibrillary acidic protein.

et al., 2013). The spectrum of noncystic WMI or “punctate” lesions has recently been described as linear or cluster lesions with different evolutions over time (Kersbergen et al., 2014). There is, however, unexplained variability in the nature of lesions detected at different centers, which may reflect differences in management, clinical acuity, or modes of detection. In particular, MRI may not fully define early diffuse lesions, and disparities between clinical presentation and the distribution of lesions on MRI have been widely noted. Experimental studies (see Fig. 60.5D–F) demonstrated that early WMI is particularly well visualized at high magnetic field

strength (12 T) (Riddle et al., 2011), which suggests that currently used clinical MRI field strengths of 1.5 to 3 T may be a limiting factor to detect both diffuse WMI and microcysts.

It should also be emphasized that preterm survivors frequently display diffuse abnormalities in gray and white matter maturation by virtue of their preterm birth that may be more common than focal or diffuse WMI (Chau et al., 2013). These diffuse abnormalities are apparent on MRI as enlarged subarachnoid spaces, a reduction in the amount of white matter, ventriculomegaly, and impaired gyral development (Skranes et al., 2013; Engelhardt et al., 2015).

However, many premature newborns do not have these dramatic abnormalities, and up to 20% with adverse outcomes do not have significant qualitative abnormalities on MRI (Miller et al., 2005; Boardman et al., 2007).

Physiologic Factors Related to the Pathogenesis of White Matter Injury

Role of Hypoxia–Ischemia

HI contributes to the pathogenesis of preterm cerebral injury via several maturation-dependent mechanisms. Since measurements of CBF are technically challenging in human preterm neonates, experimental studies have often been used to define the role of CBF disturbances in the generation of cerebral WMI. The developmental epoch when CBF disturbances occur is a critical factor that influences susceptibility to hypoxia–ischemia. For example, acute injury to the cerebral cortex is relatively low compared with that to the white matter in the preterm fetal sheep, even with prolonged ischemia, whereas severe panlaminar cortical necrosis occurs in term animals (Reddy et al., 1998; Riddle et al., 2006). After global cerebral hypoperfusion, midgestation sheep displayed a predilection to periventricular and subcortical WMI, whereas near term animals displayed predominantly parasagittal cortical neuronal injury (Reddy et al., 1998; Raad et al., 1999; Riddle et al., 2006). Cerebral ischemia in conjunction with hypoxia appears to be a critical factor to generate significant preterm WMI. WMI was infrequently observed when a restriction in uteroplacental blood flow resulted in decreased oxygen delivery to and mild acidemia in the fetus without systemic hypotension or cerebral hypoperfusion (Rees et al., 1997; Mallard et al., 1998; Rees et al., 1999). Similarly, in models of maternal fetal infection, preterm ovine WMI was observed only when repeated systemic fetal endotoxin exposure resulted in both transient hypoxemia and hypotension (Duncan et al., 2002; Dalitz et al., 2003).

Pressure–Passive Circulation

Disturbances in cerebral autoregulation appear to be a key factor that predisposes preterm neonates to cerebral WMI from hypoxia–ischemia. *Cerebral autoregulation* refers to the maintenance of constant CBF over a range of changes in systemic arterial blood pressure or cerebral perfusion pressure (Lassen and Christensen, 1976; Paulson et al., 1990; Greisen, 2009). This autoregulatory range has both upper and lower limits. When blood pressure changes above or below these limits, CBF fails to remain constant and increases or decreases passively, along with changes in arterial blood pressure. Preterm infants are particularly prone to display a “pressure–passive” circulation, especially in the setting of critical illness. Cerebral autoregulation disturbances in premature infants were initially studied by means of xenon clearance and Doppler and more recently by near-infrared spectroscopy and spatially resolved spectroscopy (du Plessis, 2008; Greisen, 2009). Severe perinatal asphyxia, hypoxia, head trauma, and hypercapnic acidosis, even when relatively mild, attenuate or even abolish autoregulation (Busija and Heistad, 1984; Tweed et al., 1986; Jones et al., 1988). Cerebral autoregulation appears to involve an intrinsic property of arterial smooth muscle cells that respond to changes in transmural pressure to modify muscle tone. Autoregulation may be mediated in part by a balance between endothelial cell–derived constricting and relaxing factors (Iadecola and Nedergaard, 2007). Fundamental questions regarding cerebral autoregulation remain unanswered,

including the optimal clinical practices for blood pressure regulation (Greisen, 2009).

Factors That Influence the Distribution of White Matter Injury

Multiple factors that influence CBF or white matter metabolism determine the severity of WMI. It was originally proposed that the topography of more severe WMI was determined by the distribution of arterial end and border zones within the white matter. This attractive hypothesis provided an explanation for the propensity of more cystic necrotic lesions to localize to the deeper periventricular white matter. It was proposed that when periventricular white matter flow falls below a critical threshold, periventricular white matter would sustain greater WMI relative to a putatively better-perfused cerebral cortex. It has been feasible to test this hypothesis experimentally, but not in humans. Quantitative measurements of fetal CBF were done in utero in histopathologically defined regions of cerebral cortex and white matter in preterm fetal sheep (McClure et al., 2008). In the setting of moderately severe ischemia, no pathologically significant gradients of fetal blood flow were detected between cerebral cortex and periventricular white matter during either ischemia or reperfusion. Moreover, although WMI preferentially localized to deeper white matter regions, they were not susceptible to greater ischemia (Fig. 60.6). Neither were less vulnerable superficial regions of white matter characterized by greater blood flow during ischemia. As discussed earlier, the distribution of WMI was explained by the relatively higher density of preOLs in susceptible regions of white matter.

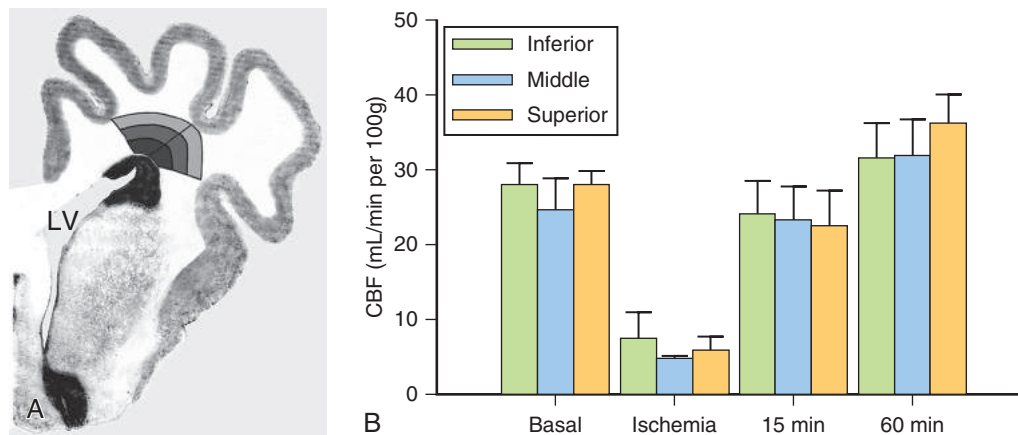

It is also currently unclear if recurrent HI predisposes to more severe WMI. In preterm-equivalent neonatal rats, a pronounced increase in cell death was observed in chronic WMI after recurrent HI (Segovia et al., 2008). However, in preterm fetal sheep, whose lesions more closely resemble those of humans, recurrent HI did not trigger enhanced WMI, which suggested that recurrent HI may confer protection against more severe WMI through an ischemic tolerance-like mechanism (Hagen et al., 2014).

Clinical Factors Related to the Severity of White Matter Injury

Several common clinical conditions have been associated with increased risk of more severe WMI (Box 60.2). Among these is neonatal sepsis, which occurs in up to 25% of preterm newborns who weigh less than 1500 g at birth (Stoll et al., 2002b; Bizzarro

• BOX 60.2 Pathogenic Factors Contributing to More Severe White Matter Injury

- Postnatal sepsis may promote postnatal cerebral hypotension or modify the response to hypoxia–ischemia.
- More severe hypoxemia coupled with hypotension may increase the magnitude of energy failure mediated by hypoxia–ischemia.
- Hypocarbica may exacerbate hypoxia–ischemia by promoting more severe hypoperfusion.
- Hypoglycemia may exacerbate energy failure associated with hypoxia–ischemia.
- Steroid exposure (e.g., dexamethasone) may increase the risk of white matter injury.
- Exposure to multiple painful or stressful procedures may increase the risk of white matter injury.

• **Fig. 60.6** Periventricular White Matter Injury Is not Explained by Gradients of Reduced Cerebral Blood Flow in Cerebral White Matter. (A) Analysis of fetal sheep cerebral blood flow (CBF) in preterm cerebral white matter during hypoxia–ischemia and reperfusion. CBF measurements were made in inferior, middle, and superior regions of the white matter, as illustrated (gray gradient). Typically, white matter injury localized to the inferior region of the white matter. (B) There were no differences between baseline CBF values and those obtained during ischemia or reperfusion at 15 or 60 minutes after ischemia in inferior, middle, and superior regions of the white matter. Hence white matter injury was not preferentially associated with regions that sustained the most severe ischemia. LV, Left ventricle. (From McClure M, Riddle A, Manese M, et al. Cerebral blood flow heterogeneity in preterm sheep: lack of physiological support for vascular boundary zones in fetal cerebral white matter. *J Cereb Blood Flow Metab.* 2008;28:995–1008.)

et al., 2005; Makhoul et al., 2005) and is associated with a significantly increased risk of WMI (Glass et al., 2008; Shah et al., 2008; Chau et al., 2009). Postnatal infections have been linked to altered development of white matter pathways (Inder et al., 2003b; Adams et al., 2010) and widespread impairments in brain development (Chau et al., 2012). Even without culture-proven sepsis, infections have been associated with increased rates of cerebral palsy and other neurodevelopmental disabilities that are consistent with neonatal brain imaging findings (Stoll et al., 2004; Miller et al., 2005; Shah et al., 2008; Chau et al., 2012). Recurrent postnatal infection is an important risk factor for progressive WMI (Glass et al., 2008). Postnatal infections and hypotension, but not histologically defined chorioamnionitis, were associated with increased risk of MRI-defined WMI (Chau et al., 2009). Despite the lack of strong associations between prenatal chorioamnionitis and adverse neurodevelopmental outcomes, chorioamnionitis may indirectly increase the risk of postnatal infections and hypotension as independent risk factors for cerebral ischemia and WMI. In a single center, the incidence of punctate WMI appears to be decreasing over time; in this cohort prolonged exposure to indomethacin predicted reduced WMI (Gano et al., 2015).

Bronchopulmonary dysplasia (BPD) and the number of days of mechanical ventilation have been associated with adverse white matter and cortical development (Anjari et al., 2009; Kaukola et al., 2009; Ball et al., 2010). Although a history of BPD is a strong predictor of cognitive outcome, even after birth weight and neurologic morbidity have been controlled for (Short et al., 2003), a causative role for isolated hypoxemia in WMI remains unclear from clinical or experimental studies (Back and Rosenberg, 2014). Postnatal exposure to corticosteroids for the prevention and treatment of chronic lung disease may impair brain growth, and this effect may be more pronounced with dexamethasone treatment (Murphy et al., 2001; Lodygensky et al., 2005). Postnatal exposure to corticosteroids, used for the treatment of BPD or low blood pressure, is also associated with impaired growth of the cerebellum (Tam et al., 2011a).

Hypoxemia, as an independent risk factor for WMI, was proposed on the basis of a suspected association between cystic WMI and BPD (Ment et al., 1998). However, a direct association between hypoxemia from chronic lung disease and severe WMI is difficult to establish, because cystic WMI is also commonly associated with IVH and PVHI. The response of the fetus to acute hypoxemia without ischemia has been extensively studied in preterm fetal sheep. Transient hypoxemia was found to cause variable degrees of combined WMI and gray matter injury in the midgestation or near term sheep (Penning et al., 1994; Rees et al., 1997, 1999). However, WMI was notably more severe when significant hypotension was observed, which resulted in *both* cerebral hypoxia and ischemia (Ting et al., 1983). Midgestation chronic hypoxemia, generated by chronic placental insufficiency, caused disturbances in hippocampal, cerebellar, and white matter development (Penning et al., 1994; Rees et al., 1999). Exposure of neonatal rodents to chronic hypoxia results in a spectrum of somatic and cerebral growth retardation that is accompanied by disturbances in white matter development that include ventriculomegaly, reduction in white and gray matter volumes, and disrupted myelination (Ment et al., 1998; Turner et al., 2002; Back et al., 2006; Scafidi et al., 2014). However, central features of human preterm WMI, such as preOL degeneration and reactive gliosis, are not observed in rodents. It thus appears that chronic hypoxemia is related to disturbances in white matter maturation that are distinct from the injury generated by acute hypoxia–ischemia.

Hyperoxia is also a potential complication of neonatal resuscitation and ventilation of the preterm infant during intensive care, but a direct association with human preterm WMI has not been demonstrated. A rabbit model of neonatal resuscitation found no increase in IVH or cerebral injury in response to hyperoxia (Chua et al., 2010). Tissue culture models of hyperoxia have demonstrated enhanced vulnerability of preOLs to cell death from oxidative stress, and transient disturbances in myelination in neonatal rodents were observed (reviewed in Back and Rosenberg, 2014).

Both hypocarbia and hypercarbia have been associated with more severe WMI and IVH, which appear related to disturbances in CBF (Greisen and Vannucci, 2001). A dramatic decline in the incidence of cystic periventricular leukomalacia appeared to be related to a decrease in the number of days of mechanical ventilation (Hamrick et al., 2004b), possibly by avoiding hypocarbic alkalosis, which can promote hypotension. Hypocarbia was identified as a potential risk factor for more severe WMI in early studies (Fujimoto et al., 1994; Dammann et al., 2001; Okumura et al., 2001; Giannakopoulou et al., 2004). Cumulative exposure to hypocarbia but not hyperoxia (Wiswell et al., 1996) was associated with an increased risk of more severe cystic WMI. The deleterious effect of cumulative hypocarbia but not hyperoxia was confirmed in a large study of nearly 800 infants (Shankaran et al., 2006). Hypercarbia promotes increased CBF and WMI in association with more severe IVH (see earlier). Permissive hypercapnia has been widely used as a strategy to deliver a high partial pressure of carbon dioxide to reduce lung injury in mechanically ventilated preterm infants. Trials of permissive hypercapnia found no evidence of cystic WMI by cranial ultrasound evaluation (Mariani et al., 1999; Carlo et al., 2002). Although a more recent small study similarly found no increase in overt WMI in response to hypercarbia, abnormal white matter microstructure was identified when ELBW infants were evaluated at term by diffusion tensor MRI (Ou et al., 2014).

WMI is a prominent and common feature of symptomatic hypoglycemia in term infants that has a predilection for the posterior limb of the internal capsule and posterior cerebral regions. WMI often occurs in association with cortical or subcortical gray matter abnormalities seen on MRI (Burns et al., 2008). Experimental studies support the observation that even mild hypoglycemia exacerbates cerebral injury from HI (Yager et al., 1992; Vannucci and Vannucci, 2001). Studies in preterm fetal sheep (Fig. 60.7) found that hypoglycemia was the most significant factor associated with more severe WMI generated by global cerebral HI (Riddle et al., 2013).

Preterm infants are often routinely exposed to multiple painful and stressful procedures that have been linked to altered brain

• **Fig. 60.7** Blood Glucose and Oxygen Levels Influence the Severity of White Matter Injury. Studies in preterm fetal sheep analyzed the severity of white matter injury (WMI) in chronic lesions after hypoxia-ischemia. The spectrum of WMI severity was estimated by quantification of the magnitude of reactive astrocytes (glial fibrillary acidic protein [GFAP] area fraction on the z-axis) in the lesions. Those sheep with the greatest degree of WMI showed a combination of reduced CaO_2 and blood glucose levels, while those sheep with less severe WMI had higher CaO_2 and blood glucose levels. (From Riddle A, Maire J, Cai V, et al. Hemodynamic and metabolic correlates of perinatal white matter injury severity. *PLoS One*. 2013; 8:e82940.)

maturation that involves white and gray matter structures, as well as impaired brain function (Smith et al., 2011; Brummelte et al., 2012). Procedural pain has also been linked with impaired postnatal growth (Vinall et al., 2012), a predictor of poor cortical development (Vinall et al., 2013a). More recently, analgesic and sedative medication exposure in the preterm neonate have been linked to regional dysmaturation, specific to the exposure: increasing midazolam exposure predicts slower growth of the hippocampus (Duerden et al., 2016), whereas increasing morphine exposure predicts slower growth of the cerebellum (Zwicker et al., 2016). Exposure to painful procedures is also associated with more adverse neurodevelopment, which is influenced by parent–child interactions (Tu et al., 2007; Grunau et al., 2009), as well as parental stress and anxiety (Perlman, 2002; Benzie et al., 2013). Importantly, experimental and human studies support the potential of parent–infant interactions to compensate for compromised early brain maturation and adversity (Vazquez et al., 2000; Tu et al., 2007; Brummelte et al., 2011; Bagot et al., 2012; McManus and Poehlmann, 2012; Vinall et al., 2013b).

Pathogenesis of Chronic White Matter Injury

Emerging Roles for Myelin in Brain Development, Learning, and Memory

Myelination disturbances are one of the central features of chronic WMI. Myelination begins in the preterm brain and normally progresses in well-defined sequences that continue for years postnatally. The central role of myelin is to wrap axons to ensure optimal nerve conduction throughout the CNS. However, emerging studies are challenging the long-held belief that myelin is a stable structure that simply provides static insulation to nerve fibers. Recent studies report that myelin sheaths are dynamic structures that contribute importantly to learning and memory by remodeling the thickness of myelin sheaths so as to enhance or diminish the relative strength of nerve conduction. Hence adaptive myelin plasticity appears to provide a mechanism whereby the nervous system can strengthen or weaken the flow of information along competing pathways so as to optimize new learning (Fields, 2015). Whereas synaptic plasticity operates on millisecond dynamic timescales to fine-tune learning and memory, myelin plasticity occurs on longer timescales to enable the nervous system to solidify the acquisition of new skills. For example, in adult animals, generation of new oligodendrocytes and myelin is required for the learning and acquisition of new motor skills (Gibson et al., 2014; McKenzie et al., 2014).

Hence the definition of these new roles for myelin underscores the potential impact that WMI may have on the disruption of the timing and sequences of myelination during a critical period in preterm brain development. Preterm brain development involves multiple cell maturational and activity-dependent events that coincide with sequential waves of late neurogenesis, gliogenesis, glial and neuronal maturation, synaptogenesis, and myelination. Aberrant myelination is likely to disrupt both gray matter and white matter development by causing enduring disturbances in the ultimate establishment of neural networks and connectivity that are integral to normal brain function.

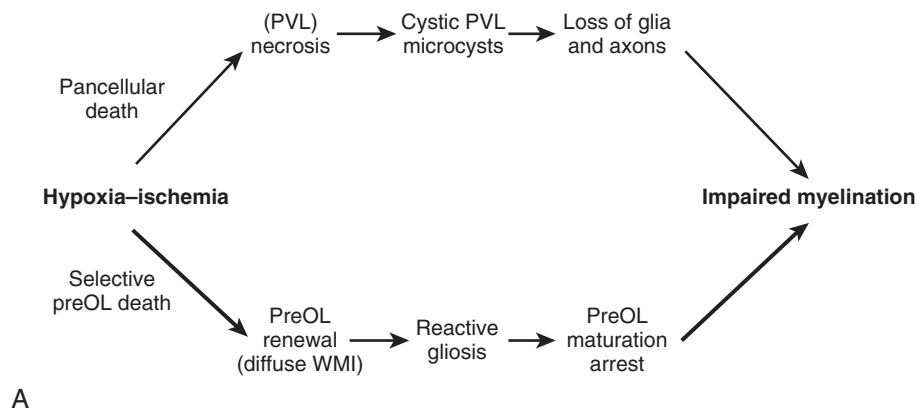

Pathogenesis of Chronic Myelination Failure and Potential Therapeutic Strategies

Myelination disturbances are related to aberrant regeneration and repair responses to acute death of preOLs. The preterm developing brain contains a population of early preOLs that serve as an apparent

reservoir of cells that can mount repair responses after WMI. In response to preOL death, early preOLs rapidly proliferate and partially differentiate to regenerate preOLs that are killed in early WMI (Segovia et al., 2008; Buser et al., 2012). Thus the preterm human white matter is capable of mounting a robust repair response to injury. Despite this inherent plasticity, the injured white matter displays robust astrogliosis, which diffusely extends beyond the core of injury as a functional “glial scar” that blocks the normal maturation of preOLs to myelinating cells (Buser et al., 2012). Hence the pathogenesis of chronic diffuse WMI leads to a disruption of the normal progression of myelination through a series of dysmaturation events that result in regeneration of preOLs that accumulate in chronic lesions but fail to differentiate to myelinating

oligodendrocytes (Fig. 60.8). By contrast, focal necrotic WMI results in a loss of both glia and axons that causes an irreversible block on myelination (see Fig. 60.8).

The mechanism by which this glial scar contributes to myelination failure is an active area of investigation. It appears likely that pronounced disturbances in the composition of the extracellular matrix result in the generation of inhibitory molecules that block preOL maturation. One widely studied molecule is hyaluronic acid, which is generated by reactive astrocytes within the glial scar and is digested by hyaluronidases that are upregulated in response to WMI (Back et al., 2005a; Preston et al., 2013; Hagen et al., 2014). These hyaluronidases generate bioactive fragments of hyaluronic acid that block preOL maturation. Preclinical studies

• **Fig. 60.8** Pathogenesis of Myelination Failure in Chronic Diffuse White Matter Injury. (A) Distinctly different pathogenetic mechanisms mediate abnormal myelination in focal necrotic lesions (periventricular leukomalacia [PVL]; *upper pathway*) versus lesions with diffuse white matter injury (WMI; *lower pathway*). When it is most severe, hypoxia-ischemia (HI) triggers white matter necrosis (*upper pathway*) with pancellular degeneration that depletes the white matter of glia and axons. Severe necrosis results in cystic PVL, whereas milder necrosis results in microcysts. Milder HI (*lower pathway*) selectively triggers early oligodendrocyte progenitor (preOL) death, but preOLs are rapidly regenerated in chronic lesions enriched in reactive astrocytes that contribute to a block in preOL differentiation to myelinating oligodendrocytes. Myelination failure in diffuse WMI thus results from preOL arrest rather than axonal degeneration, as occurs with white matter necrosis. Note that the lower pathway is the dominant one for many contemporary preterm survivors, whereas the minor upper pathway reflects the declining burden of white matter necrosis. (B) Typical appearance of normal early myelination in neonatal rodents. Axons are visualized in red and early myelination of axons is in green. (C) Arrested maturation of preOLs in a chronic white matter lesion where numerous preOLs (green) are seen, but the axons (red) are diffusely unmyelinated. Scale bars 100 μ m. HI, Hypoxia-ischemia; PreOL, oligodendrocyte progenitor; PVL, periventricular leukomalacia; WMI, white matter injury.

demonstrated that functional remyelination was promoted by a broad-spectrum hyaluronidase inhibitor (Preston et al., 2013). The downstream signaling involved in chronic WMI appears to include Wnt pathway members as well as epidermal growth factor receptor-mediated pathways (Fancy et al., 2011; Scafidi et al., 2014). It is currently unknown whether this chronic injury environment will have a negative influence on stem cell-based therapies to promote myelination (Goldman et al., 2008; Webber et al., 2009).

Since multiple signaling pathways appear to be involved in the pathogenesis of chronic WMI and myelination failure, one potential therapeutic strategy is to target multiple signaling pathways via the pleiotropic growth factor erythropoietin (Epo), which is widely used to stimulate neonatal erythropoiesis. Epo is currently under evaluation as a protective agent for WMI, because of its demonstrated actions to promote angiogenesis, neurogenesis, and gliogenesis during normal brain maturation (Juul et al., 2015). A randomized controlled trial of repeated intravenous administration of recombinant high-dose Epo to preterm neonates in the first 2 days of life was found to be safe and was associated with enhanced white matter maturation as defined by diffusion tensor imaging (Fauchere et al., 2015; O’Gorman et al., 2015), but 2-year neurodevelopmental outcomes were not improved (Natalucci et al., 2016). The Preterm Erythropoietin Neuroprotection (PENUT) trial, which randomized neonates born between 24 and 27% weeks’ gestation to high-dose Epo therapy for 2 weeks followed by maintenance Epo therapy until 32 completed weeks, is ongoing (Juul et al., 2015). Potential benefit for neonatal encephalopathy in term infants was demonstrated in a recent double-blinded, placebo-controlled trial of Epo administered with therapeutic hypothermia. A significant reduction in MRI-defined brain injury was observed in the perinatal period as was improved motor function at 1 year of age (Wu et al., 2016). Several phase III trials to test the efficacy of Epo as a neurotherapeutic for hypoxic ischemic encephalopathy (HIE) are ongoing or planned.

Preterm Cerebral Gray Matter Injury

Several neuroimaging studies have identified significant reductions in the growth of human cortical and subcortical gray matter structures, including the basal ganglia, thalamus, hippocampus, and cerebellum (Srinivasan et al., 2007; Tam et al., 2009; Keunen et al., 2012; Nossin-Manor et al., 2012; Vinall et al., 2013a). Consistent with the findings of these structural studies, preterm newborns at term age also exhibit reduced functional connectivity between the cortex and thalamus on functional connectivity MRI (Smyser et al., 2010). Children and adults born preterm with normal neurocognitive function nevertheless express altered cortical activation and functional connectivity during language and visual processing (Gozzo et al., 2009; Narberhaus et al., 2009; Schafer et al., 2009; Doesburg et al., 2011, 2013). Thalamocortical connections are also disrupted in preterm newborns with WMI, resulting in visual dysfunction (Counsell et al., 2007). Altered functional connectivity in children and adolescents born preterm is thus a significant risk factor for adverse neurocognitive outcomes (Gozzo et al., 2009; Schafer et al., 2009; Mullen et al., 2011).

The relative contributions of destructive versus dysmaturational processes to these common structural, functional, and neurobehavioral abnormalities are under active investigation. Two complementary potential mechanisms may explain impaired cerebral growth in preterm survivors. The first may involve primary degeneration of neurons in multiple cortical and subcortical gray matter structures or secondary neuronal degeneration related to axonal injury in foci of white matter necrosis. Subplate neurons,

for example, were proposed to be particularly vulnerable to HI in neonatal rodents. Subplate neurons are a transient population required to establish cortical circuitry through guidance cues for thalamocortical connections. They were reduced in a number of human autopsy cases with diagnosed necrotic WMI (Kinney et al., 2012). These findings are consistent with the link between impaired thalamocortical connectivity and cognitive delays in preterm children (Ball et al., 2015). Similarly, in rodents, significant subplate neuron loss appears to occur only in association with more severe cortical neuronal degeneration (McQuillen et al., 2003; Okusa et al., 2014). Human autopsy studies also found neuronal loss in the cortex, basal ganglia, thalamus, and cerebellum in association with necrotic WMI and axonal degeneration (Pierson et al., 2007; Andiman et al., 2010; Nagasunder et al., 2011; Kinney et al., 2012). The apparent mechanism relates to retrograde degeneration of neurons in response to axonal injury in the white matter. As discussed earlier (see Fig. 60.4A–C), axonal injury is a prominent feature of WMI where necrosis is present (Kinney and Back, 1998; Haynes et al., 2008). Significant axonal degeneration in diffuse nonnecrotic WMI (Fig. 60.9) has not been observed in either human or experimental models (Buser et al., 2012; Riddle et al., 2012). Hence primary or secondary neuronal degeneration appears to occur in the setting of more severe cerebral injury, where cystic necrotic WMI would also be common.

However, as noted earlier, white matter necrotic lesions are a minor component of diffuse WMI in experimental models and in contemporary cohorts of human WMI cases (Riddle et al., 2011; Buser et al., 2012). In human autopsy cases with early diffuse WMI and preOL degeneration, neither the preterm gray matter nor the preterm white matter displayed evidence of significant oxidative stress to degenerating neurons or axons (Fig. 60.10; Back et al., 2005b). Significant early neuronal loss was not observed in association with human nonnecrotic diffuse WMI (Back, 2005; Pierson, 2007). Diffuse WMI thus triggers selective preOL degeneration but appears to spare axons and migrating neurons in the white matter.

These observations support the theory that significant neuronal loss may be uncommon in contemporary cohorts of preterm survivors. Consistent with these observations, these infants have more extensive gray matter abnormalities than “injuries” identified by MRI signal abnormalities. To define the underlying cellular responses that accompany impaired cerebral gray matter growth, we have a model of global preterm ischemia in preterm fetal sheep. This model closely reproduces the spectrum of WMI and gray matter injury in humans (Back et al., 2012). In fact, diffuse WMI in preterm fetal sheep resulted in reduced growth of the cerebral cortex (Dean et al., 2013) and caudate nucleus (McClendon et al., 2014) without loss of neurons. These experimental findings are consistent with observations of microstructural dysmaturation of the cerebral cortex in preterm neonates with restricted postnatal growth (Vinall et al., 2013a). Reduced cerebral growth was accompanied by a significant *reduction* in the complexity of the dendritic arbors of the major populations of cortical and caudate projection neurons (Fig. 60.11). Importantly, during normal fetal sheep and human development, significant cerebral cortical growth is accompanied by a pronounced *increase* in the dendritic arbor of projection neurons. These morphologic disturbances in dendritic maturation on dysmature projection neurons were accompanied by significant reductions in the density of dendritic spines, which are the major sites where synaptic transmission occurs. Indeed, electrophysiologic studies found significant persistent abnormalities in excitatory synaptic activity at 1 month after preterm HI

• **Fig. 60.9** Axon Degeneration Is Uncommon in Chronic Diffuse White Matter Injury. White matter injury resulted from hypoxia–ischemia in preterm fetal sheep. Injured axons were identified by electron microscopy, since optimal markers of axon degeneration have not been developed for light microscopy. (A) Normal preterm white matter contained numerous axons with normal axoplasm and intact microtubules. A swollen degenerating axon (arrow) was rarely seen in control white matter. (B) Regions of diffuse white matter injury were very similar to normal controls in the paucity of degenerating axons. (C) By contrast, regions of focal white matter necrosis (i.e., periventricular leukomalacia) contained large areas devoid of axons (asterisks) as well as numerous degenerating axons (arrows). Scale bars 2 μ m. (From Riddle A, Maire J, Gong X, et al. Differential susceptibility to axonopathy in necrotic and non-necrotic perinatal white matter injury. *Stroke*. 2013;43:178–184.)

(McClendon et al., 2014). The reduced synaptic activity of these projection neurons is thus consistent with the notion that dysmaturation of the dendritic arbor of projection neurons is accompanied by disturbances in neuronal function. Hence these findings support the observation that milder forms of cerebral injury nevertheless result in impaired cerebral growth that involves disturbances in neuronal maturation that affect large distinct populations of neurons in multiple cortical and subcortical gray matter structures.

Since disturbances in maturation of preterm neurons occur at a critical window in the establishment of human neuronal connections, even transient neuronal dysmaturation may have persistent global effects on the subsequent development of CNS circuitry.

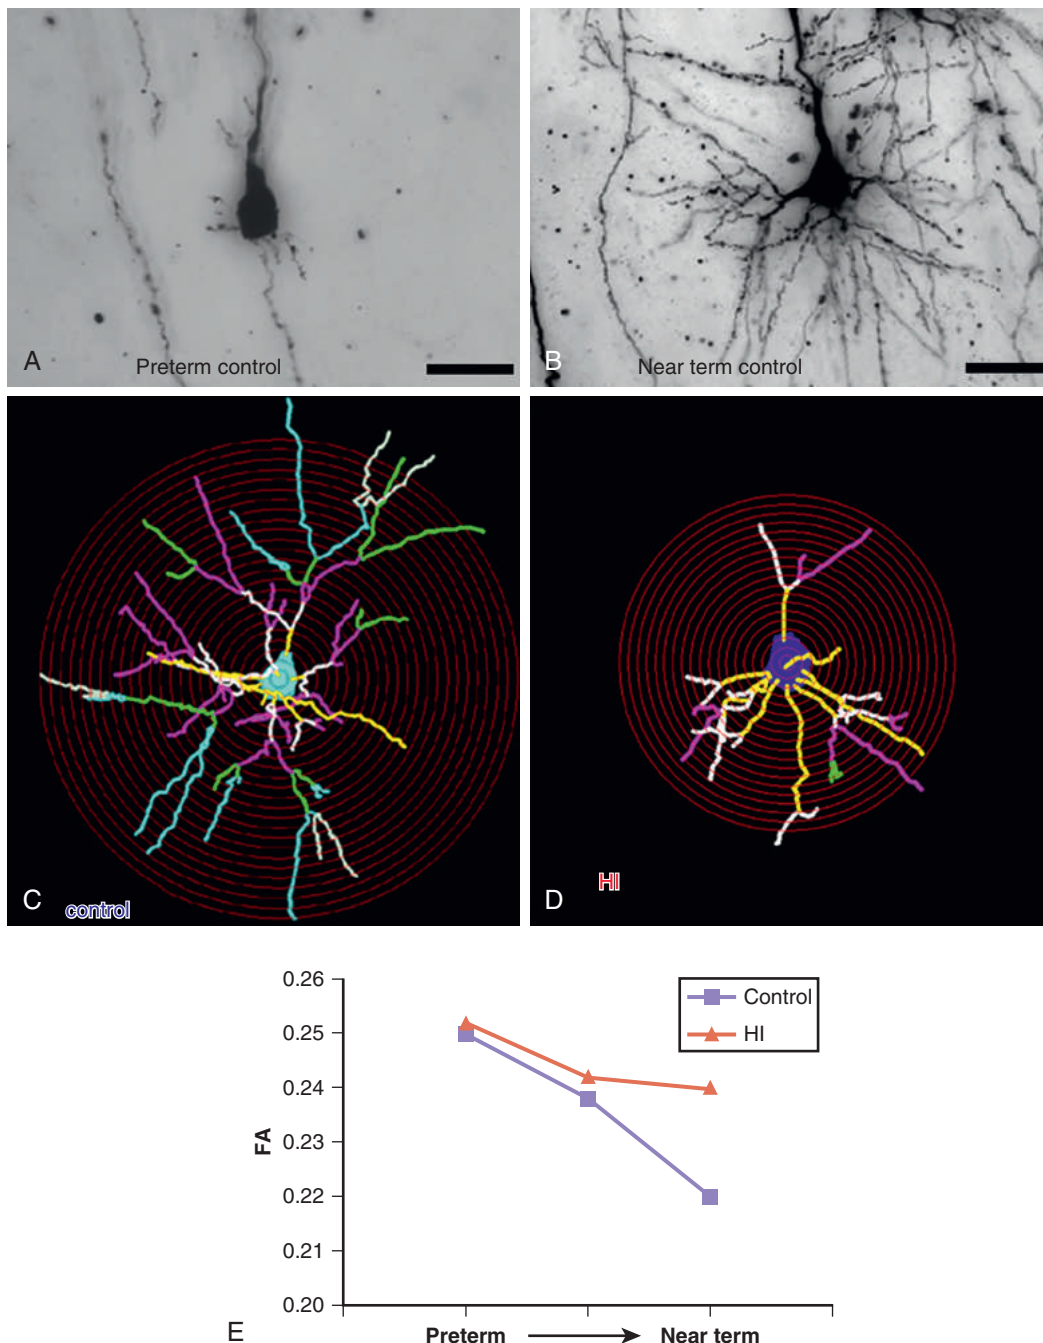

Consistent with this notion, recent neuroimaging studies have evaluated whether reduced cerebral growth is accompanied by disturbances in the microstructure of the developing cerebral cortex. During normal development, the cerebral cortex displays a normal progressive loss of cortical fractional anisotropy. This loss of anisotropy is related to the progressive maturation of cortical projection neurons (Dean et al., 2013), which are the major population of neurons in the cortex. Immature cortical projection neurons display an “anisotropic morphology” related to their simplified dendritic arbor, which causes asymmetric diffusion of water along their dendrites. As neuronal maturation progresses, the dendritic arbor assumes an “isotropic morphology” in which

• **Fig. 60.10** In contrast to oligodendrocyte progenitors, neurons and axons are markedly more resistant to oxidative injury in gray and white matter. (A) Typical paucity of cell death in the overlying cerebral cortex from a preterm infant with diffuse white matter injury at autopsy. Cell death is visualized in (A–C) by TUNEL staining, which detects DNA fragmentation of apoptotic and necrotic cells. The arrow marks the pial surface. (B, C) The periventricular white matter from the same case showed extensive oligodendrocyte progenitor degeneration. The individual degenerating cells appear as *bright green dots*. (D, E) When compared with controls, no significant oxidative injury to the cerebral cortex was observed in autopsy brains where significant preterm white matter injury was observed. Oxidative injury was measured with two very stable markers optimized for preterm human autopsy brains: F2-isoprostanes are a general marker of oxidative injury to cells and F4-neuroprostanes specifically detect injury to neurons and axons. Scale bars: (A, C) 200 μ m; (B) 100 μ m. PWMI, Preterm white matter injury. (Adapted from Back SA, et al. Selective vulnerability of preterm white matter to oxidative damage defined by F2-isoprostanes. *Ann Neurol*. 2005;58:108-120.)

water diffusion along dendritic processes is similar in all directions. Thus dysmature cortical projection neurons have a simplified dendritic arbor that results in greater “anisotropic morphology.” This reduced dendritic arbor complexity accounted for the greater anisotropy that was observed experimentally in chronic white matter lesions relative to the reduced anisotropy in normal white matter (see Fig. 60.11E). In the setting of reduced cortical growth, the gray matter of human preterm survivors was found to display increased anisotropy, consistent with greater dysmaturity (Ball et al., 2013; Vinall et al., 2013a). Disturbances in cortical fractional anisotropy were associated with impaired somatic growth (weight, length, and head circumference), even after coexisting brain injuries

on MRI (e.g., WMI) and other aspects of systemic illness (e.g., infection) had been accounted for (Vinall et al., 2013a). Improved microstructural white matter development and less IVH are linked to higher postnatal docosahexaenoic acid levels, suggesting the potential of nutrition strategies to promote optimal brain maturation (Tam et al., 2016). Hence multiple factors, including nutritional status and exposure to cerebral ischemia, may contribute to the pathogenesis of neuronal dysmaturity in preterm survivors. Further studies are needed to define how disturbances in neuronal maturation contribute to the widespread disturbances in cerebral connectivity that appear to underlie the enduring neurocognitive and behavioral deficits observed in preterm survivors.

• **Fig. 60.11** After hypoxic-ischemic white matter injury, the preterm brain is enriched in immature neurons that do not degenerate but are highly susceptible to impaired maturation that manifests itself as a less complex dendritic arbor. (A) A typical pyramidal projection neuron from the preterm cerebral cortex of a control fetal sheep that was visualized with a Golgi silver stain. Note the paucity of processes and the simplified appearance of this typical preterm neuron. (B) Neurons undergo a dramatic increase in complexity of the dendritic arbor in near term animals. (C, D) Four weeks after preterm ischemia, cortical projection neurons display disrupted maturation. A typical control neuron (C) displays highly arborized dendrites, whereas a brief preterm exposure to hypoxia-ischemia resulted in neurons with a significantly more simplified dendritic arbor (D). The reduced complexity of the dendrites can be appreciated from the overlay of the red concentric Scholl rings, which illustrate that the processes of the dysmature neurons intersect less frequently with the rings. The yellow, white, pink, green, and blue lines represent first-order, second-order, third-order, fourth-order, and fifth-order branches respectively from the soma. Note the overall reduction in the size and complexity of the branching pattern of the ischemic neurons in (D). (E) Reductions in cortical growth also manifest themselves as disturbances in cortical fractional anisotropy (FA), a magnetic resonance imaging measure of maturation and complexity of the white matter microstructure. Note the normal progressive decline in FA in controls (blue) between preterm and near term cortical development. In response to ischemia, higher cortical anisotropy (more restricted water diffusion) was observed in response to ischemia (red) relative to controls (blue), which was related to the reduced complexity of the dendritic arbor of the ischemic neurons, for example, in (D) versus controls, for example, in (C). Scale bars: (A, B) 20 μ m. FA, Fractional anisotropy; HI, hypoxia-ischemia. (From Back SA, Miller SP. Brain injury in premature neonates: a primary cerebral dysmaturation disorder? *Ann Neurol*. 2014;75: 469–486.)

Summary

Advances in neonatal neurologic intensive care have been accompanied by considerable progress in the reduction in the incidence and overall severity of IVH in preterm neonates. These advances have contributed to similar reductions in the incidence of more severe cystic necrotic cerebral WMI and gray matter injury. Unexpectedly, despite these pronounced reductions in injury severity, neurodevelopmental morbidity persists at very high rates (Synnes et al., 2010). Preterm neonates are surviving with an evolving constellation of motor, cognitive, and behavioral disabilities that appear to be related to a broad spectrum of injury that ranges

from relatively uncommon severe forms of injury to more moderate injury that is accompanied by widespread disturbances in cellular maturation. This translates to large numbers of brain cells that fail to fully mature during a critical window in development of neural circuitry. These recently recognized forms of cerebral gray and white matter dysmaturation raise new diagnostic challenges and support the urgent need for new therapeutic strategies focused on regeneration and repair to reverse the processes that promote dysmaturation.

Brain Injury in the Term Infant

RYAN MICHAEL McADAMS AND CHRISTOPHER MICHAEL TRAUDT

KEY POINTS

- Hypoxic–ischemic encephalopathy (HIE) is a major cause of neonatal brain injury and mortality worldwide.
- Magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) are useful imaging tools to identify brain injury and help predict long-term neurodevelopmental outcomes in neonates with hypoxic–ischemic encephalopathy.
- Cerebral arterial or venous thrombosis may be the cause of unexplained seizures.
- Infections acquired in utero can be detected after birth.
- Neonates with congenital heart disease (CHD) have a high incidence of brain abnormalities based on neuroimaging and are at increased risk for neurodevelopmental impairment.

Hypoxic–Ischemic Encephalopathy

Worldwide, hypoxic–ischemic encephalopathy (HIE) is the leading cause of neonatal brain injury (Wu et al., 2004) and neonatal mortality (Black et al., 2010), with neurodevelopmental impairments (NDIs) such as intellectual disability, cerebral palsy (CP), hydrocephalus, and seizures noted in approximately 50% of survivors. Intrapartum hypoxic events caused an estimated 717,000 deaths in 2010 (~1 in 5 of all neonatal deaths worldwide) (Liu et al., 2012). Motor disabilities and long-term NDIs including cognitive, neuropsychological, educational, and behavioral problems are common in surviving neonates with moderate-to-severe HIE (Marlow et al., 2005; van Handel et al., 2007). Brain injury secondary to hypoxia ischemia during labor has been noted in up to 14.5% of term born children with CP (Eunson, 2015). The emotional impact and costs associated with medical and rehabilitative care of infants with HIE are substantial (Wang et al., 2008). The Centers for Disease Control and Prevention estimated the lifetime costs for all people with CP born in 2000 to be US\$14.7 billion (~US\$1.2 million per person with CP) (Centers for Disease Control and Prevention, 2004).

Etiology

The etiology of HIE is multifactorial, but typically results from a serious hypoxic–ischemic event (acute or prolonged) occurring before or during labor or at delivery. Hypoxia leads to cardiac and vascular compromise, with subsequent diminished cerebral perfusion

and oxidative metabolism that may result in various degrees of hypoxic–ischemic brain injury. Underlying factors associated with these hypoxic–ischemic events include maternal problems associated with poor placental perfusion (e.g., maternal hypotension, preeclampsia, chronic vascular disease), primary placental perfusion problems (tight nuchal cord, prolapsed cord, true knot, abruptio placenta, or uterine rupture), and fetal oxygenation/perfusion problems (e.g., fetomaternal hemorrhage, fetal thrombosis). The etiology of HIE is often based on speculation and is challenging to determine definitively. Placental analysis has an important role in investigating potential factors that may contribute to fetal compromise and lead to HIE (fetal thrombotic vasculopathy, chronic villitis with obliterative fetal vasculopathy, chorioamnionitis with severe fetal vasculitis, or meconium-associated fetal vascular necrosis) (McDonald et al., 2004; Redline, 2005). Neonates with HIE often have placental abnormalities, particularly neonates without clinically recognized sentinel birth events. In these neonates, severe acidosis and inflammatory placental pathology are common (Chang et al., 2012). Intrapartum inflammatory factors, including maternal fever, chorioamnionitis, and prolonged rupture of membranes, may increase the risk for HIE (Blume et al., 2008).

Diagnosis

Birth History and Delivery Room Presentation

The diagnosis of HIE is made by careful birth history, neurologic examination, and laboratory studies. Birth histories consistent with HIE include descriptions of intrauterine distress (evidenced by fetal heart rate tracing abnormalities) (Murray et al., 2009), meconium passage, or a history of difficult labor and delivery (Box 61.1). Following delivery, newborns with HIE typically have respiratory failure requiring positive pressure ventilation, often needing endotracheal tube intubation with assisted ventilation. Newborns with HIE may also develop cardiac arrest requiring cardiopulmonary resuscitation and epinephrine. Low Apgar scores (<5) at 5 and 10 minutes of age are consistent with an acute peripartum or intrapartum event resulting in HIE. Neonates with HIE who sustained an intrapartum hypoxic event typically have a fetal umbilical artery pH of less than 7.0 or base deficit greater than or equal to 12–15 mmol/L or both (Neonatal encephalopathy and neurologic outcome, 2014).

Clinical Signs and Symptoms

The timing, degree, and duration of impaired cerebral perfusion and hypoxia impact the severity of brain injury in term newborns

• BOX 61.1 A Sentinel Hypoxic or Ischemic Event Occurring Immediately Before or During Labor and Delivery

A ruptured uterus
Severe abruptio placentae
Umbilical cord prolapse
Amniotic fluid embolus with coincident severe and prolonged maternal hypotension and hypoxemia
Maternal cardiovascular collapse
Fetal exsanguination from either vasa previa or massive fetomaternal hemorrhage
A ruptured uterus

TABLE 61.1 Clinical Staging of Hypoxic–Ischemic Encephalopathy

| | Stage 1 (Mild) | Stage 2 (Moderate) | Stage 3 (Severe) |
|------------------------------|---------------------|-----------------------|----------------------------|
| Consciousness | Hyperalert | Lethargic or obtunded | Stupor or coma |
| Activity | Normal | Decreased | Absent |
| Neuromuscular control | | | |
| a. muscle tone | Normal | Mild hypotonia | Flaccid |
| b. posture | Mild distal flexion | Strong distal flexion | Intermittent decerebration |
| c. stretch reflexes | Overactive | Overactive | Decreased or absent |
| Primitive reflexes | | | |
| a. suck | Weak | Weak or absent | Absent |
| b. Moro | Strong | Weak, incomplete | Absent |
| c. tonic neck | Slight | Strong | Absent |
| Autonomic function | | | |
| a. pupils | Dilated | Constricted | Variable, unequal |
| b. heart rate | Tachycardia | Bradycardia | Variable |
| Seizures | None | Common | Uncommon |

Modified from Sarnat, HB, Sarnat M. Neonatal encephalopathy following fetal distress. A clinical and electroencephalographic study. *Arch Neurol.* 1976;33:696–705.

with HIE. At birth, neonates with HIE are depressed and manifest clinical symptoms consistent with neurologic injury within the first few hours after delivery. The clinical presentation of affected neonates may evolve over a period of 72 hours and is often categorized using Sarnat staging, a classification scale originally based on the assessment of neonates over 36 weeks' gestation (Table 61.1) (Sarnat and Sarnat, 1976). Neonates presenting with a Sarnat stage 1 (mild encephalopathy) appear hyperalert with wide-open eyes, often with a “stunned look” or a blank stare, and dilated pupils. These neonates typically have normal tone but a heightened Moro

reflex reactive to tactile stimuli, bright light, or loud noises. Neither clinical nor subclinical electrographic seizures are typically noted in neonates with Sarnat stage 1 HIE. Neonates with Sarnat stage 2 (moderate encephalopathy) present lethargic with low tone, a weak suck, constricted pupils, a decreased Moro reflex, and often have clinical seizures. Severely brain-injured neonates, presenting with Sarnat stage 3 (severe encephalopathy), appear stuporous with flaccid tone, intermittent decerebrate posturing (rare), absent reflexes (suck, gag, and Moro), and poorly reactive pupils. Respiratory disturbances are also common with moderate and severe HIE, with periodic breathing and apnea present in most affected neonates (Sasidharan, 1992).

HIE is the most common cause of seizures in the neonatal period, a time period characterized by a developmental mismatch between excitatory and inhibitory states of various neurotransmitter systems, including glutamate receptors (*N*-methyl-D-aspartate, [NMDA]; α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, [AMPA]; and kainite receptors) and γ -aminobutyric acid (GABA) receptors (Shetty, 2015). Clinically apparent seizures may be noted in the first 24 hours after birth. Seizures are often subtle in presentation, manifested as abnormal eye movements (e.g., tonic, horizontal eye deviation with or without jerking, eyelid blinking), oral–buccal–lingual movements (e.g., sucking or lip smacking), or limb movements (e.g., swimming motions or bicycle pedaling). Apneic events and vital sign instability may also be presentations of seizure activity. Electrographic seizures without clinical correlate may also be present, and therefore the American Clinical Neurophysiology Society has recommended conventional continuous video-electroencephalogram (cEEG) through cooling and rewarming for neonates with moderate or severe encephalopathy. Alternatively, amplitude-integrated electroencephalography (aEEG) may be used as a screening device.

Serial examinations and monitoring are important to properly assess neonates with HIE since the clinical signs and symptoms often evolve over time. Neonates with mild HIE may develop a normal examination by 12 hours of age, whereas neonates with more severe HIE remain stuporous, often with respiratory failure and dilated pupils that are fixed or poorly reactive to light. Severely affected neonates may show some improvement in consciousness after 72 hours; however, most of them will have abnormal tone (hypotonia > hypertonia), pronounced feeding difficulties (e.g., diminished suck and gag reflexes, problems with swallowing), and varying degrees of limb weakness. In general, neonates who have a quick clinical recovery and a normal examination at 1 week of age typically have normal long-term outcomes.

Laboratory and Ancillary Studies

Laboratory tests and ancillary studies are helpful in assessing newborns with suspected HIE. Multisystem organ failure is common in babies with HIE, evidenced by metabolic and hematologic abnormalities, hepatic, renal, gastrointestinal, and cardiac dysfunction. While most neonates with brain injury from intrapartum fetal asphyxia sustain multiorgan injury, in cases of severe, acute, intrapartum asphyxia, neonates may present with evidence of brain injury without multiorgan dysfunction (Martin-Ancel et al., 1995; Phelan et al., 1998). A basic metabolic panel and an arterial blood should be obtained shortly after delivery since metabolic complications such as hypoglycemia, hypocalcemia, hyponatremia, hypoxemia, and acidosis are frequently seen. A serum lactate is often elevated following hypoxia or ischemia, reflecting anaerobic metabolism of glucose for energy in the setting of decreased tissue

oxygenation. A complete blood count will facilitate assessment of leukopenia or a leukocytosis, which may suggest infection, a hematocrit will assess for anemia (e.g., in cases of known or suspected abruption), and platelet counts will assess for thrombocytopenia, which may occur with disseminated intravascular coagulopathy (DIC). Coagulation studies to assess for DIC and to guide clinical management should be performed if clinically suspected. Infants with DIC have a prolonged prothrombin time and activated partial thromboplastin time, a decreased fibrinogen level, and increased fibrin degradation products, such as D-dimer. Liver function may be abnormal and can be assessed by checking serum alanine transferase, aspartate transferase, alkaline phosphatase, lactate dehydrogenase, total protein, serum albumin, bilirubin (total and direct), and an international normalized ratio (Shastri et al., 2012). Initial newborn creatinine levels may reflect maternal values, but a rising creatinine, especially in the setting of poor urine output, is consistent with acute kidney injury. Electrocardiography, echocardiogram, and cardiac enzymes (serum creatine kinase, creatine kinase-MB isoenzyme, and troponin I) can be obtained to assess cardiac injury and/or dysfunction, which is often present with HIE (Agrawal et al., 2012; Shastri et al., 2012). Neonates with HIE often have decreased heart rate variability on continuous electrocardiography (Matic et al., 2013; Vergales et al., 2014). Lumbar puncture should be performed if the history is not consistent with perinatal distress, to rule out conditions that may mimic HIE, such as meningitis. Other causes of neonatal encephalopathy, such as sepsis, metabolic disorders, arterial or venous stroke, cerebral dysgenesis, congenital neuromuscular disorders, and inborn errors of metabolism may also present similarly to HIE and should be considered in the differential diagnosis.

Electroencephalography

In neonates with moderate or severe HIE, monitoring for the presence of electrographic seizures is strongly recommended. cEEG is currently the gold standard for identifying neonatal seizures; however, aEEG is a commonly used monitoring tool for assessing cortical electrical activity trends and detecting electrographic seizures (Shah et al., 2014). In neonates with HIE monitored by cEEG, treatment of electrographic seizures is associated with decreased seizure burden, which may be important since an increased seizure burden is associated with increased brain injury on magnetic resonance imaging (MRI) and worse long-term outcomes (Shah et al., 2014; Srinivasakumar et al., 2015). An abnormal aEEG background pattern has been shown to correlate with an abnormal MRI in uncooled patients, but therapeutic hypothermia decreases this association (Padden et al., 2015).

Neuroimaging

Cranial ultrasonography (US) can be used as a first-line imaging tool in newborns with HIE since it can be performed at the bedside in these critically unstable neonates. While subtle signs of HIE may be difficult to detect with US, in cases of severe HIE, US may demonstrate increased focal or diffuse brain parenchyma echogenicity, slit-like ventricles, and obliteration of the extracerebral cerebrospinal fluid (CSF) spaces and the interhemispheric fissure (Dinan et al., 2014). US may also provide preliminary information about brain malformations or other potential causes of neonatal encephalopathy that may present as HIE. Although US is a valuable tool to assess neonates with suspected brain injury, MRI is the study of choice for neonates with HIE. In nondysmorphic encephalopathic newborns, MRI done in the first week after birth (after rewarming, day 4–5) can assess for injury patterns consistent with HIE and

rule out other differential diagnoses, including neurogenetic, neurovascular, or inflammatory diseases requiring intervention (Miller et al., 2002). Using a combination of conventional imaging (T1- and T2-weighted images), diffusion-weighted imaging (DWI), diffusion tensor imaging, and MRI/magnetic resonance spectroscopy (MRS) can provide information on microstructure, connectivity, and brain metabolism and assist with determining the timing of brain injury in newborns with HIE (Barkovich et al., 2006; Neonatal encephalopathy and neurologic outcome, 2014). MRI performed in the newborn period has a high predictive value in neonates, with and without therapeutic hypothermia treatment, for subsequent neurologic impairment at 18 months of age (Rutherford et al., 2010a). DWI, which measures the random Brownian motion of water molecules within a voxel of tissue, can identify early ischemic brain neonatal tissue but may underestimate the final extent of basal ganglia and thalamic lesions (Rutherford et al., 2010b). As MRI techniques have continued to evolve, allowing for more insight into the extent and patterns of brain injury, computed tomography (CT) is less often used to assess newborns with suspected HIE. In addition to concerns for radiation exposure, CT lacks the sensitivity to evaluate the characteristics and extent of brain injury in term encephalopathic infants (Neonatal encephalopathy and neurologic outcome, 2014).

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) allows noninvasive, continuous bedside monitoring of cerebral hemodynamics and oxygenation. In neonates with HIE treated with hypothermia, regional cerebral blood flow measured by MRI strongly correlates with mixed venous saturation values measured by NIRS (Spearman correlation coefficient $r = 0.88$; $P = .0085$) (Wintermark et al., 2014). In neonates with HIE treated with hypothermia, aEEG background patterns at 24 hours of age have a decreased positive predictive value, whereas the mean tissue oxygenation index (reflecting oxygen saturation in veins, capillaries, and arteries), measured by NIRS at 12 hours of age, correlates with outcomes, with significantly higher cerebral oxygenation levels seen in neonates who had a poor outcome compared to those with normal outcomes (Ancora et al., 2013). More studies are needed to establish the diagnostic and predictive value of NIRS in neonates with HIE treated with hypothermia.

Brain Injury Patterns

The neuropathology and pathogenesis of neonatal brain injury associated with HIE have been thoroughly described by Volpe, who recognizes four major neuropathologic varieties: (1) selective neuronal necrosis (most common), (2) parasagittal cerebral injury, (3) periventricular leukomalacia, and (4) focal ischemic brain necrosis (Volpe, 2008). Under the first category of selective neuronal necrosis, different injury patterns may occur depending on the insult severity and duration: a *diffuse pattern* secondary to a very severe and prolonged insult (all levels of neuroaxis affected), a *cerebral cortical–deep nuclear pattern* because of a moderate-to-severe and prolonged insult (involving cerebral neocortex, hippocampus, and basal ganglia thalamus), and a *deep nuclear–brainstem pattern* associated with a severe and abrupt insult (basal ganglia–thalamus–brainstem involvement). Diffuse cortical injury involving the basal ganglia and thalamus (Fig. 61.1) is more common in neonates who had an emergent cesarean delivery, an intense resuscitation, more severe encephalopathy, and an increased seizure burden and is associated with worse motor impairment and cognitive outcomes at 30 months of age (Miller et al., 2005). Parasagittal cerebral

• **Fig. 61.1** A Term Male Neonate With Severe Hypoxic–Ischemic Encephalopathy. (A) Axial diffusion-weighted image and corresponding (B) apparent diffusion coefficient map shows widespread, patchy cytotoxic edema involving both cerebral cortex, as well as deep nuclei and corpus callosum. (C) Axial T2-weighted image shows patchy cortical T2-weighted signal abnormality as well. (D) Dark signal in the lower medial right cerebellar hemisphere seen on axial T2-weighted image indicates intraparenchymal cerebellar hemorrhage. (Images courtesy of Dr. Francisco Perez and Dr. Teresa Chapman, Seattle Children’s Hospital, Seattle, WA.)

injury, also referred to as a *watershed predominant pattern*, is associated with partial prolonged intrapartum hypoxia and involves the parasagittal white matter with cortical gray matter involvement in severe insults. Parasagittal cerebral injury leads to cognitive deficits more often than functional motor deficits (Miller et al., 2005).

Mechanisms of Injury

Global ischemic events may cause decreased perfusion and injury to vulnerable watershed regions of the developing brain dependent on dual blood supply from the most distal branches of two large arteries

(e.g., anterior and middle cerebral arteries [MCAs]). Poor perfusion leads to a lack of oxygen and glucose, resulting in energy failure and loss of mitochondrial function, which is the central cellular problem underlying HIE. Without sufficient glucose and oxygen, adenosine triphosphate (ATP) production diminishes and energy-dependent membrane pumps fail, resulting in disrupted cellular ion gradients, neuronal membrane depolarization, neurotransmitter release (e.g., glutamate), increased cytosolic calcium levels, induction of destructive enzymes (e.g., phospholipases, proteases, and endonucleases), and free radical damage. Activated phospholipases (e.g., phospholipase A2) hydrolyze cellular membrane phospholipids and release free fatty acids such as arachidonic acid, which can increase glutamate release, uncouple oxidative phosphorylation, and inactivate membrane sodium/potassium-ATPase, resulting in cell damage. Proteases degrade cytoskeletal proteins, and cyclooxygenases stimulate arachidonic acid and prostaglandin production, which can perpetuate membrane peroxidation. Excitotoxic glutamate receptor-mediated injury can occur through overactivation of voltage-dependent and calcium-permeable NMDA receptors, causing neuron depolarization and intracellular calcium accumulation, which triggers apoptosis. Activation of AMPA glutamate receptors may result in necrotic death of mature oligodendrocytes, which are key myelin-producing cells (Leuchtmann et al., 2003).

If the newborn is resuscitated after a hypoxic-ischemic event, brain tissue reperfusion occurs, which may propagate a complex series of cellular events that evolve rapidly through amplifying signaling cascades that involve reactive oxygen species, reactive nitrogen species, cytokines, and caspases (cysteine-specific proteinases) that induce cell dysfunction and/or death. Cell death may occur by a number of processes such as necrosis (organelle swelling and vacuolation, cell membrane integrity loss, and random chromatin digestion), apoptosis (chromatin aggregation, nuclear and cytoplasmic condensation, formation of membrane-bound apoptotic bodies), and autophagy, a self-degradative process that involves proteolytic degradation of cytosolic components at the lysosome (large numbers of cytoplasmic vacuoles, partially condensed nuclear chromatin, and preservation of cellular integrity) (Northington et al., 2011).

Management of Hypoxic-Ischemic Encephalopathy

Initial management steps should focus on promoting adequate oxygenation, ventilation (i.e., securing an airway), and circulation. Serial monitoring of laboratory tests (e.g., blood gas, basic metabolic panel, ionized calcium, lactate, complete blood count, liver enzymes, and coagulation studies) and correction of metabolic derangements (e.g., hypoglycemia, hyperglycemia, and hypocalcemia) should be performed. Clinical and electrographic seizure activity should be assessed (e.g., with cEEG or aEEG) and controlled to limit further neurologic injury (Bjorkman et al., 2010; van Rooij et al., 2010). Inotropic agents may be required to correct hypotension, and echocardiography is useful to assess for evidence of myocardial dysfunction. Neonates with HIE often have renal injury manifesting with oliguria or anuria with elevated creatinine levels. Close monitoring of electrolytes and fluid restriction to limit edema is recommended. Hyponatremia may result from fluid overload from renal dysfunction and/or decreased urine output from syndrome of inappropriate secretion of antidiuretic hormone. Therapeutic hypothermia is standard-of-care for infants with moderate and severe HIE in developed countries and should be implemented within 6 hours after delivery, with timely referral to a center with a hypothermia program as needed. Passive cooling to $33^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$

can be done before active head or whole-body cooling, but active cooling during transport is recommended if possible. Cooling should be done at centers with available support from neurology (access to cEEG or aEEG), neuroradiology (access to MRI), and other services such as nephrology, gastrointestinal, cardiology, extracorporeal life support (ECLS), physical therapy, and nutrition services.

Prognosis

Accurate prediction of short-term and long-term outcomes in babies with HIE remains a challenge and requires further study, particularly in the setting of therapeutic hypothermia (Ahearne et al., 2016). An early normal neurologic examination (in uncooled neonates) is associated with favorable developmental outcomes at 2 years of age, whereas an early abnormal neurologic examination has limited long-term predictability. An abnormal examination noted at the time of discharge correlates significantly with adverse outcomes (Murray et al., 2010). Similarly, a normal MRI in the first week is associated with normal outcomes, while outcomes with watershed or basal ganglia injury on MRI are more uncertain. Deep gray matter injury on MRI correlates best with poor outcomes. MRS can also be helpful in prognosticating, as a low *N*-acetylaspartate (NAA) peak and high lactate peaks correspond to severe injury. Research to discover predictive HIE-associated biomarkers is ongoing.

Apgar Score

The Apgar score is subjective and cannot distinguish the severity of HIE. Apgar scores have limited utility in predicting long-term outcomes, as illustrated by the National Institute of Child Health and Human Development Neonatal Research Network whole-body cooling randomized controlled trial follow-up study, in which 1 in 5 babies with an Apgar score of 0 at 10 minutes survived to school age without moderate or severe disability (Natarajan et al., 2013).

Seizures

An increased seizure burden and excessive EEG discontinuity correlate with worse brain injury on MRI and are predictive of abnormal neurodevelopmental outcome in neonates treated with therapeutic hypothermia (Briatore et al., 2013; Dunne et al., 2017). Postnatal evaluation 3–6 hours after birth of term newborns with suspected HIE using aEEG appears to reliably predict neurodevelopmental outcome. Flat tracing (very low voltage, isoelectric tracing with activity below $5\ \mu\text{V}$), continuous extremely low voltage (around or below $5\ \mu\text{V}$), and burst-suppression (discontinuous background pattern with periods of inactivity intermixed with higher amplitude bursts) patterns are predictive of poor long-term outcomes (follow-up range of 12 months to 6 years) (Toet et al., 1999). During therapeutic hypothermia, from 48 hours of age, aEEG shows accurate prediction of long-term (18–24 months) outcomes (Cseko et al., 2013). Return of sleep-wake cycling on aEEG is a favorable prognostic indicator (Osredkar et al., 2005; Cseko et al., 2013). A normal EEG pattern at 6 hours of age has a 100% positive predictive value for a normal outcome at 2 years (Murray et al., 2009).

Magnetic Resonance Imaging and Spectroscopy

MRI and MRS are useful in predicting outcome in neonates with HIE (Goergen et al., 2014; Hayakawa et al., 2014; Nanavati et al., 2015). Ischemia patterns on MRI (done in the first week after birth) correlate with neurodevelopmental outcomes at 2 years of age; favorable outcomes are associated with watershed patterns, whereas central and diffuse patterns of ischemia are associated with unfavorable outcomes (Twomey et al., 2010). Diffusion tensor

imaging facilitates evaluation of the location, orientation, and integrity of white matter pathways by determining water molecule diffusion patterns in white matter tracts (Choudhri et al., 2014; Massaro et al., 2015). Diffusion tensor imaging abnormalities (at median of 8 days of age) of the corpus callosum and corticospinal tract in neonates with HIE treated with hypothermia predict poorer cognitive and motor performance, respectively, in early childhood (15 to 21 months of age). Higher basal ganglia and thalamic perfusion demonstrated at postnatal age of 4.5 days (range 2–7 days) with arterial spin labeling MRI, a noninvasive technique to evaluate brain perfusion, are associated with adverse outcomes at 9–18 months of age in neonates who had HIE (De Vis et al., 2015). Additional studies correlated with long-term outcomes are needed to clarify the utility of newer MRI techniques for diagnostic, prognostic, and therapeutic purposes.

Hypoxic-ischemic injury may lead to neuronal death with associated decreased NAA levels and impaired mitochondrial and oxidative metabolism associated with increased brain lactate levels. Based on metaanalysis of 32 studies, involving 860 infants with HIE, deep gray matter (thalamic or basal-ganglia) lactate/NAA is the most accurate quantitative magnetic resonance biomarker for predicting neurodevelopmental outcomes (at ≥ 12 months of age; Thayil et al., 2010).

Outcomes

Therapeutic hypothermia for neonates with moderate and severe HIE is now standard-of-care in developed countries, and this treatment has positively impacted neonatal outcomes (Jacobs et al., 2013). In term and late preterm infants with moderate-to-severe encephalopathy and evidence of intrapartum asphyxia, therapeutic hypothermia decreases the combined outcome of mortality or major neurodevelopmental disability to 18 months of age from 61% (409/666 control newborns) to 46% (312/678 treated newborns) (typical risk ratio 0.75, 95% confidence interval (CI) 0.68–0.83; typical risk difference -0.15 , 95% CI -0.20 to -0.10) (Gunn et al., 1998; Eicher et al., 2005; Gluckman et al., 2005; Shankaran et al., 2005; Azzopardi et al., 2009; Simbruner et al., 2010; Zhou et al., 2010; Jacobs et al., 2011). One out of 7 neonates with moderate-to-severe encephalopathy will benefit from therapeutic hypothermia (95% CI 5–10). Unfortunately, despite treatment with therapeutic hypothermia, 44% of neonates with moderate-to-severe encephalopathy will still die or have major long-term neurodevelopmental disabilities. Neonates with mild HIE usually have no long-term deficits, whereas those with severe HIE often die or are severely impaired with spastic quadriplegia, cortical visual impairment, and seizure disorders, despite cooling. Neonates with moderate HIE have outcomes ranging from normal to severely abnormal. A normal clinical examination at 7–10 days is encouraging for a normal long-term outcome, whereas a severely abnormal examination is concerning for a poor long-term prognosis. Early EEG at the end of the first week of age can further assist in predicting outcomes at 2 years of age (Biagioni et al., 2001).

Since prevention of HIE has not been successful, adjunctive treatments to therapeutic hypothermia are urgently needed to improve outcomes. At a global level, other interventions that might be used in low-income and middle-income countries are also needed, as therapeutic hypothermia is often not available or may even be harmful (Robertson et al., 2008). Hopefully, discovery of better biomarkers will help identify, provide insight into therapeutic options, and accurately predict outcomes in neonates with HIE.

Perinatal Arterial Ischemic Stroke

Perinatal arterial ischemic strokes (PAIS) are focal or multifocal arterial thrombosis or embolization occurring between 20 weeks' postmenstrual age and 28 days' postnatal life (van der Aa et al., 2014). The reported incidence varies between 1 in 1600 and 1 in 5000 live births (Lee et al., 2005; Laugesaa et al., 2007). The true incidence is likely to be higher given that most of the studies were retrospective and MRI was not routinely used. PAIS is more common in males and non-Hispanic black ethnicity and occurs most often in the left MCA distribution. Risk factors for PAIS include maternal primiparity, preeclampsia, prolonged rupture of membranes, chorioamnionitis, and cord anomalies (Harteman et al., 2012). Presence of more than one of these risks factors can increase the probability of PAIS to 1 in 200 (Lee et al., 2005). Complicated deliveries involving emergency cesarean section or instrumentation have also been associated with PAIS.

The pathogenesis of PAIS is not well understood. Physiologic changes in the mother during pregnancy may cause a hypercoagulable and prothrombotic state. Fetuses are also at increased risk for developing clots as physiologic polycythemia leads to hyperviscosity, and there is a depressed anticoagulant activity present. These factors, coupled with the placenta having areas of reduced blood flow, increase the proclivity for thrombotic generation on the fetal side of the placenta. These thrombi will travel via the umbilical vein and are poised to pass through the patent foramen ovale to enter the systemic and most importantly the cerebral arteries. Other fetal conditions leading to increased risk of PAIS include twin pregnancies, twin-to-twin transfusion, arteriovenous malformations, prolonged neck traction, and cardiac defects (Golomb et al., 2006; Benders et al., 2007). PAIS lesions are usually singular (70%) and isolated to the anterior circulation (71%), posterior circulation (7%), or, less commonly, both (20%) (Kirton et al., 2011). Strokes are most commonly left sided (51% all strokes, 73% of all anterior strokes), right sided (9%), or bilateral (20%) (Kirton et al., 2011).

Most infants with PAIS are asymptomatic at birth, but signs of acute illness are seen in 25% of infants with PAIS (Kirton et al., 2011). In the week following birth, most newborns with PAIS become symptomatic, with the most prevalent symptom being seizures (up to 70%–90%) (Hayward and Adappa, 2014). Diffuse neurologic signs are more common than focal signs, with abnormal tone and depressed level of consciousness more common than hemiparesis. Nonspecific symptoms include breathing and feeding difficulty.

Given that the most common presenting symptom is seizures, the work-up should begin with ruling out hypoglycemia, hypocalcemia, electrolyte disorders, infection, and metabolic syndromes. MRI is the gold standard test for the detection of PAIS. Sequences to be used include T1- and T2-weighted images, DWI, and MRI angiography. Fig. 61.2 demonstrates MRI of a term male with a PAIS involving the right MCA. Of these sequences, the most sensitive is DWI performed in the first week of life. The area of infarction appears as a zone of high intensity on DWI and low intensity on the apparent diffusion coefficient map. After the first week the ischemic tissue appears to normalize, even though the area continues to be ischemic, a process known as pseudonormalization. Reduced contrast between cortex and white matter can be seen in the first 48 hours on T2-weighted imaging. Lower signal intensity will be seen on T1-weighted images. As time from the injury passes, cortical highlighting develops.

EEG should be performed to help localize the origin of the seizures as well as management of the seizures. Cranial US is widely

• **Fig. 61.2** A 4-Day-Old Term Male Neonate With Right Middle Cerebral Artery Stroke. (A) Axial diffusion-weighted image shows abnormal bright signal throughout the right cerebral hemisphere in the middle cerebral artery territory. The corpus callosum is also involved. (B) Apparent diffusion coefficient map shows dark signal, confirming this is true cytotoxic edema. (C) Coronal T2-weighted image shows abnormal loss of gray-white matter differentiation, consistent with a subacute time frame (at least 6 hours) for the injury. A head magnetic resonance angiogram showed no definite stenotic lesion (not shown here). (Images courtesy of Dr. Randolph Otto and Dr. Teresa Chapman, Seattle Children's Hospital, Seattle, WA.)

available in most centers that do not have MRI capability. The sensitivity of US improves from 68% in the first few days to 87% in the first week (Cowan et al., 2005). Because strokes may occur in the posterior circulation, posterior fontanelle imaging is necessary. Unlike MRI, cranial US is operator dependent, and thus detection rates will vary between centers. Use of CT is limited and discouraged because of poor sensitivity and high radiation dose.

The optimal thrombosis evaluation is currently debated, and one review found the studies to be “contradictory or inconclusive due to lack of statistical power” (Kenet et al., 2010). Rates of possible thrombophilia as an underlying cause of PAIS vary in the literature up to as high as 68%. However, the International Pediatric Stroke Study found that only 19% of PAIS infants were diagnosed as having possible increased lipoprotein(a) level, methylene

tetrahydrofolate reductase mutations, elevated β_2 -glycoprotein level, factor V Leiden, prothrombin gene 20210A, low anti-thrombin III level, antiphospholipid antibodies, plasminogen activator inhibitor, or low protein S level (Kirton et al., 2011).

Therapy for PAIS is largely supportive. Anticonvulsant therapy has the best evidence for use, but most infants will not require long-term therapy, and many experts increasingly suggest early discontinuation (Kirton et al., 2011). Anticoagulation is currently debated in the literature, and the type of antithrombotic medication used varies from country to country. There is most consensus for use of anticoagulant therapy in infants with congenital heart disease (CHD) and PAIS, as they are at increased risk of ongoing clot formation (Monagle et al., 2008).

Neurodevelopmental outcomes depend on the size and location of the stroke. Mortality in PAIS is very low. PAIS occurring in the MCA territory may result in a hemiplegia rate of 50% (Chabrier et al., 2011). While most infants will be discharged seizure free, up to 50% will later develop epilepsy. Cognitive and language deficits are more common in children with hemiplegia or epilepsy following PAIS (Ricci et al., 2008). Visual function is also altered by PAIS. Behavioral problems may also be seen.

Cerebral Sinus Venous Thrombosis

Cerebral sinus venous thrombosis (CSVT) has a reported incidence of 0.6–12 per 100,000 live births (deVeber et al., 2001; Berfelo et al., 2010). The wide range of reported incidence is likely due to variable awareness among clinicians and therefore variable use of neuroimaging to detect CSVT. Impaired venous drainage from CSVT causes increased venous pressure that can result in increased capillary hydrostatic pressure. This elevated pressure leads to vasogenic edema and hemorrhagic infarction in the distribution of the cerebral sinus venous. Maternal risk factors for CSVT include preeclampsia, chorioamnionitis, and gestational diabetes. Complicated delivery, meconium aspiration, and the need to be intubated have also been associated with CSVT. Similar to PAIS, CHD is a major risk factor. Postnatal conditions such as meningitis, sepsis, dehydration, and ECLS are associated with CSVT. Presenting signs and symptoms are subtle and nonspecific: seizure is the most common symptom, but respiratory distress, lethargy, apnea, and poor feeding can also be present with CSVT.

Neuroimaging is crucial to the diagnosis of CSVT. The superior sagittal sinus has the highest rate of thrombus, followed by straight and transverse sinuses. Most neonates have multiple sinuses involved. MRI is the gold standard, especially when the MRI venography (MRV) sequence is performed (Fig. 61.3). MRI serves two purposes: (1) to document the sinus involved and (2) to identify associated lesions. CSVT can sometimes be detected by T1- and T2-weighted images. Restricted diffusion on DWI will be present in areas affected by CSVT. MRV allows the clinician to see the venous system without the use of contrast.

US can be used to diagnose CSVT; however, it has a high false-negative rate and requires operator experience in the use of Doppler to measure venous sinus flow (Miller et al., 2012). US is able to detect intraventricular and thalamic hemorrhages with ease, and CSVT should be ruled out in term neonates with unexplained intraventricular hemorrhage (Wu et al., 2003). CT has a high false-negative rate and, given the high radiation, is generally not preferred (Nwosu et al., 2008). As with PAIS, thrombophilia evaluation should be performed and should include protein-based assays as well as genetic testing. While the genetic testing can be done acutely, the protein-based studies are most frequently

performed at around 6 months of age because of the large volume of blood required for testing and also because consumption of factors during acute thrombosis may lead to inaccurate results.

Treatment of CSVT should target the inciting factor: for instance, treating dehydration, meningitis, or CHD. Thrombus progression is seen in 25% of neonates, and no complications have been seen with anticoagulation for infants with associated intracranial hemorrhages (Moharir et al., 2010). Therefore most practitioners will treat CSVT with unfractionated heparin or low-molecular-weight heparin in neonates without hemorrhage. Those with hemorrhage that show progression of the CSVT at 5–7 days should have anticoagulation therapy started. Treatment duration is between 6 and 12 weeks.

Few studies of CSVT have been performed, and follow-up data are limited. Early mortality figures showed death rates between 2% and 5%; however, more recent studies with improved detection rates of CSVT show mortality rates between 19% and 25% (Wasay et al., 2008). Of the survivors, 60%–80% develop motor impairment, including CP, cognitive delay, and epilepsy.

Neonatal Hypoglycemia

The exact level or duration of hypoglycemia that will cause injury is unknown. The literature uses variable definitions for hypoglycemia that further complicate the picture. Blood glucose values in the fetus are 70% of maternal levels and rapidly fall in the first hour after birth to as low as 25 mg/dL. The American Academy of Pediatrics guidelines for asymptomatic hypoglycemia has a cutoff of 45 mg/dL (Committee on Fetus and Newborn and Adamkin, 2011). However, the Pediatric Endocrine Society has recently published that glucose levels should be kept at greater than 50 mg/dL for the first 48 hours after birth, then at greater than 60 mg/dL after 48 hours (Thornton et al., 2015). Symptomatic hypoglycemia can manifest as cyanosis, tremors, apnea, seizures, change in consciousness, irritability, and feeding problems. Neonatal risk factors for hypoglycemia include small for gestational age, maternal diabetes, perinatal asphyxia, respiratory distress, sepsis, and congenital metabolic disorders.

The proposed mechanism of hypoglycemia-induced injury is by increased excitatory neurotransmitter levels that lead to excessive NMDA receptor activation. This activation induces increased intracellular sodium and calcium concentrations. Increased calcium influx into cells causes activation of phosphatidases and proteases, which alters mitochondrial function and generates free radicals. ATP production is hampered, which leads to apoptosis and neuronal necrosis.

Hypoglycemia may lead to brain swelling, necrosis, and white matter demyelination, especially in areas rich with NMDA receptors. Brain regions affected include the parieto-occipital cortex, corpus callosum, basal ganglia, thalamus, and posterior limb of the internal capsule. Long-term sequelae associated with hypoglycemia include visual impairment, epilepsy, and cognitive deficits. However, a recent study showed no difference in neurocognitive outcomes at 2 years of age between hypoglycemic and nonhypoglycemic neonates (McKinlay et al., 2015). The degree of injury is likely directly related to depth and duration of hypoglycemia and the presence of any comorbidities, especially HIE.

Central Nervous System Infections

Maternal infections during pregnancy and labor can affect the fetal/neonatal brain. There is a fourfold increased risk of CP in

• **Fig. 61.3** A 15-Day-Old, Former 34 Weeks' Gestation, Preterm Male Neonate With Hypoxic–Ischemic Encephalopathy and Dural Venous Sinus Thrombus. (A) Axial and (B) coronal T2-weighted images show abnormal dark signal in the medial left parietal lobe parenchyma, with surrounding high signal. (C) Axial susceptibility weighted imaging shows dark signal and blooming artifact, consistent with blood products. (D) Coronal maximum intensity projection image from a magnetic resonance venogram shows diminished flow in the lower sagittal sinus and left transverse sinus consistent with thrombus. Findings are consistent with hemorrhaging venous infarct and surrounding vasogenic edema. (Images courtesy of Dr. Jason Wright and Dr. Teresa Chapman, Seattle Children's Hospital, Seattle, WA.)

pregnancies complicated by chorioamnionitis. Pregnancies with chorioamnionitis are more likely to have additional neonatal complications such as HIE, meconium aspiration leading to pulmonary hypertension and hypoxia, sepsis, and neonatal meningitis. Pulmonary hypertension as a result of pneumonia can cause CP in 30% of term neonates as a result of synergistic injury from hypoxia and sepsis.

Meningitis

Neonates are at greater risk of meningitis than other age groups because of inefficiency of the alternative complement pathway, deficient migration and phagocytosis of neutrophils, and decreased T-cell and B-cell activity, leaving them at risk for infections with encapsulated bacteria. Group B streptococcus (GBS) is the leading

cause of meningoencephalitis in the term newborn period, followed by *Escherichia coli* and *Listeria monocytogenes*. The incidence of bacterial meningitis is 0.3 per 1000 live births. Herpes simplex virus (HSV) incidence varies from 1 per 5000 to 1 per 26,000 live births. Emerging pathogens include enterovirus, human parechovirus-3, and *Enterobacter sakazakii*.

Symptoms in the first 48 hours of age include temperature instability, apnea of bradycardia, hypotension, feeding difficulty, hepatic dysfunction, and irritability alternating with lethargy. In contrast, neurologic symptoms are more commonly seen after 48 hours of age. These include stupor, irritability, seizures, bulging anterior fontanelle, gaze deviation, cranial nerve palsies, and extensor posturing. Unlike children and adults, nuchal rigidity is not common. Any neonates with signs of sepsis or nonspecific symptoms in which meningitis might be a cause should have a lumbar puncture to examine the CSF. Many experts suggest ordering a HSV polymerase chain reaction (PCR) on all neonates with suspected meningitis. Up to one-third of infants who have negative blood cultures had positive CSF cultures, suggesting that cases of meningitis may be missed if lumbar punctures are not performed (Stoll et al., 2004). The classic findings of decreased CSF glucose, elevated CSF protein, and pleocytosis are seen more often with Gram-negative meningitis, late Gram-positive meningitis, and viral meningitis, especially caused by HSV. No single CSF parameter exists that can reliably exclude the presence of meningitis in a neonate (Garges et al., 2006).

The choice of an antibiotic regimen should be based on the likely pathogen, the local patterns of antibacterial drug sensitivities, and the policies of the hospital. Cefotaxime, in addition to ampicillin, is the usual empiric coverage used due to penetration of the blood-brain barrier by cephalosporins, but some experts suggest that ampicillin plus an aminoglycoside is a better choice because of synergy. Treatment duration is usually 14–21 days, and most experts suggest a repeat lumbar puncture 2–3 days into treatment. Corticosteroids have been shown to reduce long-term sequelae, particularly hearing loss, in older infants with *Haemophilus influenzae* type B meningitis and *Streptococcus pneumoniae* infection; however, use of corticosteroids is not recommended for neonates with meningitis (Chaudhuri, 2004). Acyclovir is the empiric treatment of choice for suspected viral meningitis.

Complications associated with meningitis include cerebral edema, hydrocephalus, hemorrhage, abscess formation, infarction, and ventriculitis. Cerebral edema occurs from direct cytotoxic cell injury, vasogenic changes, and inappropriate antidiuretic hormone secretion. Obstruction to CSF drainage can lead to hydrocephalus in up to 24% of infants. Hemorrhage and infarction can be caused by venous or arterial thrombosis. Cerebral abscess occurs in as many as 13% of neonates with meningitis and should be considered with new seizures, signs of elevated intracranial pressure (ICP), or new focal neurologic signs, and brain imaging with contrast is essential for making the definitive diagnosis (Pong and Bradley, 1999). Ventriculitis occurs in as many as 20% of neonates with meningitis and results in sequestration of infection to areas that are poorly accessible to systemic antimicrobial drugs (Unhanand et al., 1993). Inflammation of the ependymal lining of ventricles often obstructs CSF flow. Failure to respond to appropriate antibiotic therapy and signs of elevated ICP may suggest the diagnosis of ventriculitis, in which case intraventricular administration of antibiotics may be necessary.

Survivors of neonatal meningitis are at significant risk for moderate-to-severe disability, including problems with language,

motor function, hearing, vision, cognition, and epilepsy. As many as 20% of children identified as normal at 5-year follow-up may have significant educational difficulties lasting into late adolescence. Poor prognostic indicators include low birth weight, prematurity, significant leukopenia or neutropenia, high levels of protein in the CSF, delayed sterilization of the CSF, and coma. Seizures lasting longer than 72 hours and the need for inotropes predict moderate-to-severe disability or death with 88% sensitivity and 99% specificity (Klinger et al., 2000). In a prospective sample of more than 1500 neonates surviving to the age of 5 years, the prevalence of motor disabilities (including CP) was 8.1%, learning disability occurred in 7.5%, seizures in 7.3%, and hearing problems in 25.8% (Bedford et al., 2001). No problems were reported in 65% of infants who survived GBS meningitis and in 41.5% of those who survived *E. coli* meningitis.

Herpes Simplex Virus

The majority of HSV infections result from intrapartum transmission, with occasional postnatal exposure occurring through oropharyngeal shedding or cutaneous shedding of virus by parents or hospital contacts. Most neonates will present in the second postnatal week. Neonates may present with pallor, irritability, high-pitched cry, respiratory distress, fever, jaundice, seizures, hepatic dysfunction, and DIC (Kimberlin, 2004). Work-up should include HSV PCR of CSF, cultures of fluid from vesicles, and swabs of the nasopharynx, conjunctiva, and rectum. Central nervous system (CNS) infection with HSV can lead to necrotizing lesions, which result in microcephaly, porencephalic cysts, and CP. Mortality among neonates with HSV infection of the CNS is 15%. The two HSV serotypes (HSV-1 and HSV-2) carry the same risk of mortality. However, HSV-2 is more commonly associated with morbidity, including CP, intellectual disability, seizures, microcephaly, and ophthalmic defects (Kimberlin, 2004). HSV-1 infection tends to be more diffuse in neonates, instead of the medial temporal and insular involvement seen with children and adults. Although the use of acyclovir has reduced the morbidity and mortality associated with HSV infection, neurologic sequelae are likely in 50% of neonates with HSV meningitis (Kimberlin, 2004).

Toxoplasmosis

The prevalence of toxoplasmosis is 1 per 1000 live births and is caused by *Toxoplasma gondii* (Pickering, 2012). This parasite can pass the placenta from an infected mother to infect the fetus. Pregnant women are cautioned not to be exposed to cat feces and to cook meat until it is well done. Granulomatous necrosis, hydrocephalus, and calcifications in the basal ganglia and periventricular regions result from CNS infection with *T. gondii* and can be present on prenatal US. In the absence of hydrocephalus, microcephaly is also reported. Neonates can present with enlarged liver or spleen, eye drainage, feeding difficulties, intrauterine growth restriction, seizures, or tiny red spots or bruising. Congenital toxoplasmosis treatment consists of pyrimethamine, sulfadiazine, and leucovorin for up to 1 year (Petersen, 2007). Despite adequate treatment, 30% of infants with toxoplasmosis will have seizures, motor abnormalities, or blindness.

Cytomegalovirus

Cytomegalovirus (CMV) is the most common congenital viral infection, with an incidence of 0.6–0.75 of all deliveries in the

United States (Swanson and Schleiss, 2013). Transmission to the fetus can occur in primary infections of the mother or reactivation of a latent infection at any gestational age. Postnatal infection rarely causes significant illness in term newborns and is not associated with long-term disability. Congenital infections may result in intrauterine growth restriction, thrombocytopenia, hydrops, jaundice, hepatosplenomegaly, microcephaly, periventricular calcification, seizures, and sensorineural hearing loss. About 40%–58% of newborns who are symptomatic at birth go on to develop sequelae, including sensorineural hearing loss, intellectual disability, seizure disorder, CP, visual deficits, or developmental delay (Boppana et al., 1992; Dollard et al., 2007).

Diagnosis in the neonate can be made by PCR, culture, or antigen testing (pp65 antigen) of urine, blood, or saliva within the first 3 weeks of life (Bhatia et al., 2010). Antibody titers cannot reliably indicate the diagnosis, as maternal CMV immunoglobulin G crosses the placenta, and neonates mount weak immunoglobulin M responses. Complete blood count and liver function tests may reveal pancytopenia and hepatitis, and coagulation studies may be abnormal. Renal function is checked as a baseline before beginning treatment with ganciclovir. Audiologic assessment should be performed on all infants with congenital CMV infection, as sensorineural hearing loss may be absent at birth, and frequent evaluations are required throughout childhood to evaluate for the possibility of hearing deterioration (Dahle et al., 2000).

Sensorineural hearing loss can be prevented by early treatment with ganciclovir. One randomized study indicated that 84% of ganciclovir recipients either had improved hearing or maintained normal hearing between baseline and 6 months. In contrast, only 59% of control patients had improved or stable hearing (Kimberlin et al., 2003). Results were even more encouraging when the study and control groups were compared for subsequent maintenance of normal hearing, as none of the ganciclovir recipients had a worsening in hearing between baseline and 6-month follow-up, compared with 41% of control patients. The intravenous ganciclovir therapy group had fewer developmental delays at 6 and 12 months compared with untreated infants (Oliver et al., 2009).

Zika Virus

The World Health Organization declared the rapidly spreading epidemic of Zika virus (ZIKV) a “Public Health Emergency of International Concern” on February 1, 2016, based on emerging evidence that the virus might cause severe fetal brain injury, specifically, severe microcephaly (Gulland 2016a, 2016b). ZIKV is an arbovirus (mosquito-borne) member of the Flaviviridae family, which includes dengue, West Nile virus, chikungunya, and yellow fever. Recently, sexual transmission has also been documented. In adults infected with ZIKV, only 20% of individuals become symptomatic, experiencing a self-limited infection characterized by fever, rash, conjunctivitis, muscle/joint pain, and fatigue, although an estimated 1 of 200–300 infected individuals develop Guillain-Barré syndrome. In 2015, a ZIKV epidemic in Northeastern Brazil was linked with a precipitous increase in microcephaly, intracranial calcifications, and ocular abnormalities. The microcephaly appeared to be much more severe than typical microcephaly caused by other viral infections (CMV, rubella) or genetic syndromes. The affected fetal brain was often over 4 standard deviations below mean, with loss of gyri, marked hydrocephalus, and areas of brain necrosis. Vertical transmission has now been confirmed, with increased miscarriage as well as affected fetuses from all trimesters increasingly documented in endemic areas.

While many different cell lines can be infected with ZIKV, neural progenitor cells (NPCs) are a direct target of ZIKV (Tang et al., 2016). ZIKV-infected NPCs had increased cell death, downregulated proliferation, and altered neurosphere production (Garcez et al., 2016; Li et al., 2016; Tang et al., 2016). Normal brain development is highly dependent on NPC differentiation, migration, and maturation, which is impaired by ZIKV, leading to microcephaly (Li et al., 2016). Children born to ZIKV-infected mothers have shown a wide range of abnormalities, ranging from mild effects to severe microcephaly, almost agyric brains, parenchymal calcifications, hydrocephalus, and cerebellar hypoplasia (Culjat et al., 2016). It is unknown if infection after birth can lead to similar problems or if in utero infection is required to cause long-term problems. Immunization and treatments are being investigated, but for now delay of pregnancy, use of condoms, control of the *Aedes* mosquito population, and prevention of mosquito bites are the only strategies available.

Inborn Errors of Metabolism

Chronic encephalopathy results from the majority of inborn errors of metabolism. The pattern of injury is dependent on which area of the brain is most affected (gray or white matter or both, subcortical or cortical gray matter nuclei). The mechanism of action is not fully understood but involves disrupted astrocyte function, excitotoxicity, and energy failure (Gropman, 2012). A few prototypical inborn errors of metabolism will be discussed.

Phenylketonuria

Phenylketonuria (PKU) is an autosomal recessive disorder caused by a deficiency in phenylalanine hydroxylase, required to convert phenylalanine to tyrosine, which is essential to make dopamine. Dopamine is essential for prefrontal pyramidal neurons involved with working memory and inhibitory control. Prefrontal white matter pathology on structural MRI scans and diffusion tensor imaging can be seen in adults with PKU (Anderson and Leuzzi, 2010). Lifelong restriction of phenylalanine is necessary, as precipitous drops in intellectual quotient following termination of the diet occur in adults. Maternal PKU that is not well controlled is teratogenic and may result in growth retardation, microcephaly, significant developmental delays, and birth defects in offspring, regardless of whether the fetus has PKU (Levy, 2003).

Urea Cycle Disorders

Urea cycle disorders are autosomal recessive disorders with the exception of ornithine transcarbamylase deficiency, which is X-linked. Neonates with absent urea cycle enzyme activity typically present with hyperammonemic coma within the first week after birth. Outcomes can be severe, with high morbidity and mortality approaching 50% (Batshaw and Monahan, 1987). Acute hyperammonemia selectively affects the white matter of the brain and initially may be seen as reversible changes involving the deep sulci of the insular and perioral region watershed territories. Hypoperfusion associated with urea cycle disorders may play a role in causing brain injury.

Methylmalonic Acidemia

Methylmalonic acidemia (MMA) is a deficiency of the adenosylcobalamin-dependent enzyme methylmalonyl-coenzyme A mutase characterized by accumulation of methylmalonic acid.

It has an autosomal recessive inheritance. MMA typically presents in either a newborn who was healthy for the first days to weeks of life or in infants having a history of poor feeding, vomiting, progressive lethargy, floppiness, and muscular weakness. Diagnosis is by urine organic acids that demonstrate large amounts of methylmalonic acid, methylcitrate, propionic acid, and 3-hydroxy propionic acid. Plasma amino acids typically show elevation of glycine but may be normal. MRI scans typically demonstrate involvement of basal ganglia and white matter, with the globus pallidus being selectively affected (Gao et al., 2009).

Congenital Heart Disease

As survival of infants with CHD has improved, there has been more focus on assessment of long-term morbidities, particularly neurodevelopmental outcomes. Children with severe cyanotic CHD have a high incidence of brain abnormalities at birth, with further brain injury commonly diagnosed by MRI after surgical correction (McQuillen et al., 2007, 2010; McQuillen and Miller 2010; Miller et al., 2007; Dimitropoulos et al., 2013). These children are at increased risk of significant NDI, with approximately 50% of survivors affected (Martinez-Biarge et al., 2013). Whether abnormal cerebral circulation in utero results in altered brain development or impaired hemodynamics in the perioperative period leads to hypoxic brain injury needs further clarification. Doppler US scans at term and fetal brain MRI/MRS at 36–38 weeks' gestation have demonstrated that most neonates with CHD (all types) have abnormal neurodevelopmental features compared to control neonates but that abnormalities are more pronounced in CHD lesions associated with decreased oxygenated blood supply to the brain (Masoller et al., 2016). The prevalence of brain lesions has been shown to differ depending on the type of CHD, varying from 34% in cases of transposition of the great arteries to 49% in cases of left-sided heart lesions (Khalil et al., 2014). While identified genetic syndromes, present in up to 30% of children with CHD (Down syndrome and 22q11 deletion being the most common), are independent risk factors for NDI, infants with CHD have a high prevalence of brain lesions on neuroimaging even in the absence of chromosomal or genetic abnormalities and independent of the surgical risk (Marino et al., 2012). Although the brain abnormalities detected by neuroimaging in infants with CHD may increase their risk of NDI, further investigation is needed to establish causality between specific brain lesions and types of NDI in relation to specific types of CHD.

Other potential risk factors for NDI and/or biomarkers of brain injury in infants with CHD include seizures and stroke. Seizures in the newborn and in the perioperative period are common in patients with CHD. Unfortunately, seizures are often subclinical, so they may not be recognized or treated (Gunn et al., 2012; Naim et al., 2015). In the Boston Circulatory Arrest Study, which involved 171 infants with D-transposition of the great arteries who had cEEG monitoring in the first 48 hours postoperatively, seizures were detected in 20% of patients, with clinical seizures being detected in only 6% of patients (Helmers et al., 1997). Neuropsychological follow-up of 139 of these patients at 16 years of age demonstrated that a postoperative seizure was the medical variable most associated with poor outcomes (Bellinger et al., 2011). In preschool survivors who had cardiac surgery during infancy, postoperative electrographic seizures are associated with NDI, characterized by executive function impairments and a higher prevalence of deficits in social interactions and repetitive/restricted behaviors (Gaynor et al., 2013).

Similar to seizures, stroke in the newborn and in the perioperative period is common and may be clinically silent in patients with CHD. Before and after repair, stroke is seen on MRI in 10%–30% of infants with CHD (Martinez-Biarge et al., 2013). Infants with cyanotic CHD undergoing palliative surgery are most frequently affected by arterial ischemic stroke during the periprocedural period, with NDI seen in the majority of survivors (Asakai et al., 2015). Because of the increased prevalence of seizures and stroke in infants with CHD, diligent perioperative screening and long-term follow-up studies are needed to further clarify risk factors associated with CHD, with the hope that improved understanding will lead to the development of effective treatment strategies.

Bilirubin-Induced Neurologic Dysfunction and Kernicterus

Hyperbilirubinemia is very common in the newborn period and is usually not associated with negative effects in most babies. While a direct linear relationship between total serum/plasma bilirubin (TB) levels and developmental delay has not established, elevated TB levels have been associated with bilirubin neurotoxicity and long-term NDI (Maimburg et al., 2010). Increased unconjugated bilirubin levels may lead to increased unbound or “free” bilirubin, which strongly binds myelin-rich membranes, making neurons a main target of bilirubin toxicity, with bilirubin-induced brain injury primarily affecting only a subgroup of neurons in selected areas of the basal ganglia, brainstem, and cerebellum (Watchko and Tiribelli, 2013). Elevated bilirubin levels may induce nonneuronal cells such as astrocytes and microglia to produce proinflammatory cytokines that may contribute to bilirubin-induced brain injury (Brites, 2011).

Neonatal hyperbilirubinemia may lead to acute bilirubin encephalopathy, a condition characterized by lethargy and abnormal behavior, evolving to frank neonatal encephalopathy, opisthotonus, and seizures (Wusthoff and Loe, 2015). Severe hyperbilirubinemia may lead to bilirubin neurotoxicity associated with development of kernicterus, an irreversible, chronic neurologic condition characterized by choreoathetoid CP, impaired upward gaze, and sensorineural hearing loss (Kaplan et al., 2011). The estimated incidence of acute bilirubin encephalopathy/kernicterus in North America and Europe is between 0.4 and 2.7 cases per 100,000 live births among term and late-preterm neonates (born at ≥ 35 weeks' gestation) (McGillivray and Evans, 2012) but is estimated to be much higher in low-income and middle-income countries (Olusanya et al., 2014). Milder degrees of neonatal hyperbilirubinemia than those resulting in kernicterus may result in bilirubin-induced neurologic dysfunction (BIND), a severe and irreversible syndrome that manifests after the neonatal period as developmental delay, cognitive impairment, disordered executive function, and behavioral and psychiatric disorders (Johnson and Bhutani, 2011; Wusthoff and Loe, 2015). Bilirubin-associated brain injury seen in infants with BIND may occur in the basal ganglia, central and peripheral auditory and visual pathways, hippocampus, diencephalon, subthalamic nuclei, midbrain, and cerebellum.

Neuroprotection Strategies for the Newborn

SANDRA E. JUUL, BOBBI FLEISS, RYAN MICHAEL MCADAMS, AND PIERRE GRESSENS

KEY POINTS

- Neonatal brain injury may result from an interruption of normal development (predominant in preterm infants) or from damage to existing tissues (predominant in term infants).
- Current approaches to neuroprotection in preterm infants include prenatal administration of steroids, administration of magnesium sulfate, delayed cord clamping, and administration of caffeine.
- Therapeutic hypothermia is the only proven therapy for term infants with intrapartum-related complications.
- New neuroprotective approaches, including use of erythropoietin, melatonin, and stem cell therapy, are currently in clinical trials. Ideal neuroprotection will likely include multiple targeted approaches at different times.

The two most common causes of death of newborns globally are prematurity and intrapartum-related complications. The *Lancet* has repeatedly published data about the global, regional, and national causes of child death, and together these two problems consistently account for close to 50% of neonatal deaths worldwide (Black et al., 2010; Liu et al., 2012, 2015). For neonates who survive after premature delivery and/or intrapartum-related complications, the burden of disease is also enormous (Global Burden of Disease Pediatrics Collaboration, 2016). The sequelae of these problems differ with the resources available to help the child, but even in the most affluent countries, with all available treatments used, death or neurodevelopmental impairment (NDI) occurs in approximately 50% of affected infants. Children with neonatal stroke, cyanotic heart disease, pulmonary hypertension, inborn errors of metabolism, kernicterus, and fetal alcohol exposure, among other problems, are also at high risk of NDI and could potentially benefit from neuroprotection strategies. Impairment may include intellectual deficiencies, motor deficiencies, deafness, blindness, and an increased risk of problems such as autism spectrum disorder. As the field of neonatology has accomplished marvels in improving survival in recent decades, the new focus must be on helping these survivors to thrive, to live full and healthy lives without impairment. To accomplish this audacious goal, there must be new developments in neuroprotective strategies.

Mechanisms of Disease: Identification of Targets for Neuroprotection

Neonatal brain injury can occur from clastic injury (injury to existing tissues) or from an interruption or disruption of normal developmental processes. Clastic injury is most often seen in term infants, while in preterm infants, interruption of normal development is most often an important component of long-term injury.

Clastic Lesions

In experimental studies, cerebral hypoxia–ischemia of sufficient severity to deplete tissue energy reserves (primary insult) is often followed by transient but complete restoration of glucose utilization, adenosine triphosphate, and phosphocreatine on reperfusion/reoxygenation. Thereafter a secondary decrease in the levels of high-energy phosphates occurs in parallel with a decrease in tissue glucose metabolism and development of cell injury. Similarly, infants with neonatal encephalopathy (also termed *neonatal ischemic encephalopathy*) show characteristic abnormalities in cerebral energy metabolism, which is frequently normal soon after birth but shows a progressive decline in the ratio of the concentration of phosphocreatine to inorganic phosphate some hours later (Azzopardi et al., 1989). Infants displaying this phenomenon develop severe neurodevelopmental impairment or die, and there is a close relationship between the magnitude of the late decline in the ratio of the concentration of phosphocreatine to inorganic phosphate, reduced brain growth, and the severity of NDI.

These findings suggest that most of the injury associated with hypoxia–ischemia evolves over time after rather than during the insult. Hypothermia following hypoxia–ischemia takes advantage of this window and reduces secondary energy failure and brain injury (Thoresen et al., 1995). However, the mechanisms involved in secondary brain injury are incompletely understood, and such information is critical for development of the next generation of therapies to be combined with hypothermia in term infants with neonatal encephalopathy.

The deficit in high-energy phosphates induced by hypoxia–ischemia leads to a primary failure to maintain transmembrane ionic gradients, release of neuroactive compounds into the extracellular compartments, accumulation of intracellular Ca^{2+} , and the

activation of a series of mechanisms that if sustained will lead to immediate cell death. If the individual is resuscitated, these acute alterations are completely or partly reversed, but the complex process has been started in which multiple interrelated factors may produce secondary brain injury. The precise mechanisms of damage are incompletely understood, but some components of the process have been elucidated (Thornton et al., 2012). Excitatory amino acids, mitochondrial impairment (loss of mitochondrial function, altered biogenesis and fusion/fission cycle, release of factors initiating the apoptotic cascade), intracellular calcium regulation, generation of reactive oxygen species, including nitric oxide, cell death mechanisms (including different types of cell death, such as apoptosis, necroptosis, ferroptosis, parthanatos, and autophagy), changes in the availability of trophic factors, and the immunoinflammatory system are all implicated in the process. In addition, experimental evidence and some recent epidemiologic studies support the hypothesis that perinatal systemic inflammation could play a key sensitizing role to hypoxic-ischemic/excitotoxic brain insults, a process that could make hypothermia less efficient (Hagberg et al., 2015).

Interruption/Disruption of Normal Development

Until a few years ago the prevailing dogma was that, in preterm neonates, immature oligodendrocyte precursors, which are highly sensitive to oxidative stress and excitotoxicity, were dying (clastic damage), leading to white matter cysts (Volpe et al., 2011). More recent neuropathology studies have shown that these cells do not die in significant numbers but rather are largely unable to mature completely and therefore cannot contribute to axon myelination despite their presence in the white matter (Verney et al., 2012). These nonclastic white matter abnormalities most likely contribute significantly to the diffuse white matter injury described on magnetic resonance imaging (MRI) in numerous preterm infants (Rutherford et al., 2010; Kidokoro et al., 2013).

MRI studies performed in preterm infants show two key features supporting the hypothesis that changes in gray matter structures are also implicated in the pathomechanisms of encephalopathy of prematurity: (1) the connectivity between gray structures is significantly reduced, especially thalamocortical connections, and (2) the microstructure of cortical structures is reduced, although the cellular and molecular correlates are still largely unknown (Lodygensky et al., 2010). On the basis of experimental evidence, different hypotheses can be suggested: (1) reduced number of neurons and in particular of interneurons that are lately produced and could be affected by preterm birth; (2) reduced arborization of neurons; and (3) reduced spine/synapse density (Penn et al., 2015). Further studies are necessary to determine key cellular mechanisms and underlying molecular pathways so as to identify potential targets.

Epidemiologic, neuropathologic, and experimental studies have identified systemic inflammation and related neuroinflammation as a key mechanism involved in white matter maldevelopment and potentially in gray matter maldevelopment (Hagberg et al., 2015). Microglia, the resident brain macrophage, seem to play a key role in neuroinflammation and therefore appear as an appealing target for neuroprotection. However, microglia have multiple roles. They can be deleterious to the developing brain when they acquire a proinflammatory phenotype, but they can also play prerenal roles by removing debris and releasing proplastic factors. In addition, microglia play an important role in normal neurite pruning and synaptic elimination during brain development (Tay et al., 2016).

Brain damage associated with perinatal adverse events had, until recently, been considered a fixed disease. However, different lines of evidence suggest that this might not always be true (Fleiss and Gressens, 2012). According to emerging evidence, in addition to the developmental disruption associated with the initial insult to the immature brain, injury processes can persist for months to years. These “tertiary mechanisms” of damage likely include persistent inflammation and epigenetic changes and may prevent endogenous repair and regeneration. These processes, such as ongoing inflammation, may sensitize patients to further injury or could predispose them to develop age-related cognitive dysfunction. Treatment of tertiary mechanisms of damage might be possible by various means, including preventing the repressive effects of microglia and astrocyte overactivation, recapitulating developmentally permissive epigenetic conditions, and using cell therapies to stimulate repair and regeneration. Recognition of tertiary mechanisms of damage might be the first step in a complex translational task to tailor safe and effective therapies that can be used to treat the already developmentally disrupted brain long after an insult.

Therapeutic Approaches

Current Therapies for Preterm Infants: Prenatal Therapies

Steroids

Steroids given 24 hours to 7 days before delivery have long been known to reduce the risk of death or morbidity in preterm singleton pregnancies of 28 to 32 weeks' gestation with a risk reduction of more than 40% (Mwansa-Kambafwile et al., 2010; Chawla et al., 2013). The benefits include decreased early death, respiratory distress syndrome, intraventricular hemorrhage (IVH), and necrotizing enterocolitis. Despite this known benefit, change in clinical practice was slow, with use increasing from 8% in 1985 to 52% in 1995, 75% in 2000, and 85% in 2015. Recent studies have shown that prenatal administration of steroids also benefits preterm multiples and infants as premature as 22 weeks' gestation (Boghossian et al., 2016; Wei et al., 2016). Repeated courses can be given for threatened preterm birth, although the safety of more than two courses is not established, with some evidence that fetal head growth might be affected with multiple repeated courses (Whitelaw and Thoresen, 2000; Bonanno et al., 2007).

Magnesium Sulfate

Magnesium sulfate therapy is a well-studied prenatal therapy with potential to reduce cerebral palsy (CP) and improve gross motor function following preterm birth. In vitro, magnesium alleviates excitotoxic damage by binding to the magnesium site on the *N*-methyl-D-aspartate glutamate channel (Zeevalk and Nicklas, 1992). There is also evidence that magnesium can reduce secondary inflammation, decrease free radical formation, stabilize cell membranes, inhibit free radical production, and improve cardiovascular stability (Galinsky et al., 2014).

There have been five prospective randomized controlled trials to determine possible benefits of magnesium for neuroprotection. The magnesium dose in these studies differed, and the use of an infusion following a bolus dose was also inconsistent between studies. The Cochrane Collaboration published a metaanalysis of the 6145 women included in these studies in 2009 (Doyle et al., 2009). It found no difference in infant mortality but a 31% decrease in the overall incidence of CP in the magnesium-treated group,

with a relative risk (RR) of 0.68 (95% confidence interval [CI] 0.54–0.87). There was also a 39% decrease in the risk of substantial motor dysfunction among those infants who received magnesium (RR 0.61, 95% CI 0.44–0.85). There were no differences in blindness, deafness, intellectual impairment, IVH, white matter injury, low Apgar score at 5 minutes, neonatal seizures, hypotonia, need for respiratory support, bronchopulmonary dysplasia at 28 days or 36 weeks, or length of hospital stay. There were no maternal differences in mortality or obstetric complications. To avoid one child developing cerebral palsy, 63 women (95% CI 43–155) must be treated (Doyle, 2012; Jacquemyn et al., 2015).

Delayed Cord Clamping

In 2012 the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists issued a committee opinion recommending delayed umbilical cord clamping (DCC) (>30 seconds) in preterm neonates for a potential 50% reduction in IVH (Committee on Obstetric Practice, American College of Obstetricians and Gynecologists, 2012). This opinion was informed by several randomized controlled trials demonstrating increases in neonatal hematocrit, decreases in IVH, and improved physiologic stability with less need for pressor support. In follow-up studies of infants who underwent DCC versus immediate clamping, long-term benefits were noted at 18 to 22 months and 4 years of age with improved gross and fine motor scores and in social domains (Garofalo and Abenhaim, 2012; Andersson et al., 2015; Brocato et al., 2016; Rabe et al., 2016).

The optimal period of delay before clamping the umbilical cord in preterm infants is still undetermined. A prospective cohort study of infants of less than 32 weeks' gestational age compared DCC at 30–45 seconds with DCC at 60–75 seconds. Infants with the longer delay had higher hematocrits at less than 2 hours (49.2% vs 47.4%, $P = .02$), and reductions in the rates of delivery room intubation (11% vs 22%, $P = .004$), hypothermia on admission (1% vs 5%, $P = .01$), surfactant therapy (13% vs 28%, $P = .001$), intubation in the first 24 hours (20% vs 34%, $P = .004$), and any intubation (27% vs 40%, $P = .007$), and they received fewer red blood cell transfusions (20% vs 33%, $P = .008$) (Song et al., 2015). These results suggest that for preterm infants, a more prolonged placental transfusion after delivery may be beneficial.

Umbilical cord milking also holds appeal since if it provides benefits similar to those of DCC, it would allow more immediate resuscitation of critically ill infants. A recent metaanalysis of six studies (292 preterm infants underwent umbilical cord milking and 295 underwent immediate cord clamping) concluded that, similarly to DCC, umbilical cord milking also improved initial hematocrit, decreased the incidence of transfusion, with a pooled risk ratio of 0.74 (95% CI 0.61–0.90; $P = .002$), and decreased the risk of necrotizing enterocolitis, IVH, and death (Dang et al., 2015).

Caffeine

In landmark work studying the effects of caffeine on preterm outcomes in 2006 individuals, Schmidt et al. (2006) showed that in addition to reducing apnea and the need for mechanical ventilation, treatment of infants with birth weights of 500–1250 g decreased the outcome of death or survival with one or more of the following impairments: cerebral palsy, cognitive deficit, blindness, and deafness. A follow-up study that captured data from 1640 of the original 2006 babies enrolled in the Caffeine for Apnea of Prematurity (CAP) trial showed no sustained benefit, although there was a trend toward improved motor function: of the 833 caffeine-treated children,

176 (21.1%) died or survived with one or more impairments, compared with 200 of the 807 placebo-treated children (24.8%) (odds ratio adjusted for center 0.82, 95% CI 0.6521.03, $P = .09$). Further analysis has shown a lower rate of developmental coordination disorder in caffeine-treated infants compared with placebo-treated infants (Schmidt et al., 2006, 2007, 2012; Doyle et al., 2014).

Kangaroo Care

Skin-to-skin contact between a mother and a premature infant, often called *kangaroo care*, has been shown to have multiple short-term and long-term benefits. The benefits include increased physiologic stability, decreased maternal anxiety or depression, improved breastfeeding, increased pain tolerance, improved growth, and decreased mortality (Johnston et al., 2008; Athanasopoulou and Fox, 2014; Bera et al., 2014a, 2014b; Conde-Agudelo and Diaz-Rossello, 2014; Boundy et al., 2016). Scher et al. (2009) showed that skin-to-skin contact for 1.5 hours per day, 4 days per week for 8 weeks accelerated electroencephalogram (EEG) signs of brain maturation.

There are emerging long-term findings that the effects of kangaroo care can be sustained, improving attention and quality of movements (Silva et al., 2016) and enhancing child cognitive development and executive functions for up to 10 years (Feldman et al., 2014).

Therapies on the Horizon for Preterm Infants

Melatonin

Melatonin (*N*-acetyl-5-methoxytryptamine), a neurohormone derived from the amino acid tryptophan and secreted by the pineal gland, is a strong antioxidant capable of scavenging free radicals and stimulating several antioxidative enzymes, including glutathione, glutathione reductase, peroxidase, and superoxide dismutase (Reiter et al., 2000). Melatonin can directly stimulate cellular membrane G protein-coupled high-affinity melatonin receptors (melatonin receptors 1 and 2) that activate numerous second messenger cascades, which differ in cell-, tissue-, and species-specific ways. Melatonin can also induce receptor-independent intracellular activities by targeting calcium-binding proteins, cytoskeletal and scaffold proteins, and components of mitochondrial signaling (Luchetti et al., 2010). Melatonin's safety profile and antioxidant, antiinflammatory, and antiapoptotic properties have made it an attractive neuroprotective candidate for treating neonates with neonatal encephalopathy (Alonso-Alconada et al., 2013; Biran et al., 2014).

Melatonin is neuroprotective in several animal models relevant to preterm brain injury, including a neonatal mouse model of excitotoxic white matter damage (with or without systemic inflammation), a hypoxia-ischemia model of neonatal brain damage, and inflammation-induced white matter damage in fetal sheep (Ramanantsoa et al., 2013). On the basis of these preclinical data, a pharmacokinetic study was done in preterm neonates to determine the melatonin dosage that would best mimic fetal exposure to maternal secretion of melatonin in the third-trimester fetus (Merchant et al., 2013). On the basis of this pharmacokinetic study and targeting the same melatonin concentration, a randomized clinical trial with melatonin supplementation as a potential neuroprotective agent has been initiated, and the primary outcome based on MRI assessment at corrected term age should be available soon. This study is based on the hypothesis that preterm infants, who are not yet able to produce their own melatonin, might demonstrate improved neurodevelopment when exposed to appropriate in utero levels.

Melatonin also holds promise as a prenatal neuroprotectant that could be administered to pregnant women since it appears safe, crosses the placenta (Okatani et al., 1998), and crosses the blood–brain barrier (on the basis of adult rat studies) (Vitte et al., 1988). Further research is needed to clarify the mechanisms by which the pleiotropic neurohormone melatonin may regulate neuronal cell survival, brain tissue homeostasis, and neuroprotection in neonates with neonatal encephalopathy.

Erythropoietin Neuroprotection

Erythropoietin (Epo) was first discovered for its erythropoietic effects and is most commonly used to treat anemia in individuals with chronic renal failure. Epo functions by binding to homologous cell surface Epo receptors, which are prevalent on nascent red blood cells. Epo receptors are also expressed by multiple cell types in the central nervous system (Juul et al., 1998; Bernaudin et al., 1999; Mu et al., 2005), including neuronal progenitor cells (Wang et al., 2004), subsets of mature neurons (Wallach et al., 2009), astrocytes (Sugawa et al., 2002), oligodendrocytes (Sugawa et al., 2002; Genc et al., 2006; Iwai et al., 2010), microglia (Chong et al., 2003), and endothelial cells (Wang et al., 2004). Epo is produced in the brain, primarily by astrocytes, and is thought to be an important trophic factor during brain development as well as an endogenous protective factor. Brain Epo is upregulated after prolonged hypoxia, so elevated Epo levels at birth likely reflect chronic intrauterine hypoxia and may be a useful biomarker to predict increased complications of prematurity such as necrotizing enterocolitis (Holm et al., 2016). When Epo is administered exogenously for the purposes of neuroprotection, high doses are needed to penetrate the blood–brain barrier, unless the blood–brain barrier is damaged (Juul et al., 2004; Statler et al., 2007). Epo does not cross the placenta, so it cannot be given prenatally for neuroprotective purposes. Epo has antiinflammatory, antiexcitotoxic, antioxidant, and antiapoptotic effects (Sun et al., 2005; Juul et al., 2009; Rees et al., 2010) and promotes neurogenesis, oligodendrogenesis, and angiogenesis, which are essential for repair of injury and normal neurodevelopment (Shingo et al., 2001; Wang et al., 2004; Kumral et al., 2005; Iwai et al., 2007; Osredkar et al., 2010; Gonzalez et al., 2013; Wassink et al., 2017). Some of these effects may be mediated by Epo stimulation of growth factors required for normal brain growth such as brain-derived neurotrophic factor and glial cell–derived neurotrophic factor (Dzietko et al., 2004; Wang et al., 2004). Epo effects are dose dependent, and multiple doses are more effective than single doses (Kellert et al., 2007; Gonzalez et al., 2007, 2009). Epo reduces neuronal loss and learning impairment following brain injury (Demers et al., 2005; Larphaveesarp et al., 2016). It also decreases white matter injury in animal models (Savino et al., 2006; Vitellaro-Zuccarello et al., 2008; Li et al., 2009; Iwai et al., 2010; Rees et al., 2010; Zhang et al., 2010; Yamada et al., 2011). Although Epo is most often administered immediately after injury in preclinical studies, investigators have shown that even when administration is initiated as late as 72 hours or 1 week after injury, there is evidence of improved behavioral outcomes, enhanced neurogenesis, increased axonal sprouting, and reduced white matter injury (Iwai et al., 2010; Reitmeir et al., 2011; Jantzie et al., 2016; Larphaveesarp et al., 2016).

In addition to cell-specific effects in the brain, Epo increases iron utilization as erythropoiesis is increased. Iron is highly reactive and normally sequestered by transport proteins. Unbound iron produces free radicals and subsequent oxidative injury. Preterm infants have measurable free iron, the level of which increases after

transfusions of red blood cells or during metabolic instability such as sepsis (Buonocore et al., 2003; Ozment and Turi, 2009). Epo may contribute to neuroprotection in preterm infants by decreasing free iron levels and thereby ferroptosis.

Translational Trials of Neonatal Erythropoietin Neuroprotection for Preterm Infants

Two preliminary reports of preterm infants treated prospectively have shown a benefit:

1. Preterm infants weighing 500–1250 g treated with either Epo (400 U/kg three times per week, $n = 29$) or darbepoetin (10 U/kg per dose once per week, $n = 27$) from birth to 35 weeks' postmenstrual age had an average cumulative cognitive score 8–10 points higher than placebo-treated controls, with erythropoietin-treated infants earning scores of 97.9 ± 14 and darbepoetin-treated infants scoring 96.2 ± 7.3 compared with 88 ± 14 for controls ($n = 24$). Epo recipients also performed statistically better than controls on object permanence testing (Ohls et al., 2014). The combined scores for NDI or death were significantly better in the erythropoietin-treated group and the darbepoetin-treated group, with combined scores of 15.5% compared with 48.2% in the control group, and improved intellectual outcomes were sustained at 3.5–4 years of age, although the preterm infants still performed less well than age-matched term infants (Ohls et al., 2016).
2. Follow-up of extremely low birth weight infants who received Epo at 500–2500 U/kg for three doses in a phase I/II trial (Juul et al., 2008) showed that Epo treatment correlated with improvement of cognitive ($R = 0.22$, $P < .05$) and motor ($R = 0.15$, $P < .05$) scores (McAdams et al., 2013).

A randomized, double-masked phase II trial of Epo neuroprotection for preterm infants has been completed (NCT00413946). Four hundred and forty-eight infants (gestational age 26–31 weeks) were randomized to receive Epo (3000 U/kg, $n = 228$) or saline ($n = 220$) administered at 3, 12–18, and 36–42 hours after birth. The mean gestational age at enrollment was 29.3 weeks, with birth weight of approximately 1220 g. The dose and dosing regimen were found to be safe, with no increase in retinopathy of prematurity or any other complication of prematurity (Fauchère et al., 2015), and a subset of those treated with Epo were found to have improved white matter integrity on near term MRI (Leuchter et al., 2014; O'Gorman et al., 2015). However, long-term follow-up of 81% of enrolled infants at 2 years' corrected age was disappointing, showing no benefit in the primary outcome of Mental Development Index of the Bayley Scales of Infant and Toddler Development second edition or in secondary outcomes of motor development, cerebral palsy, hearing or visual impairment, or growth parameters (Natalucci et al., 2016). The authors note that the study was underpowered to detect a significant difference because the incidence of adverse outcomes was lower than expected when the study was being planned. It is also possible that a longer course of Epo is required for neuroprotection of preterm infants during the prolonged period of potential vulnerability in the initial hospitalization.

Risks of Intervention

In adults, complications of prolonged Epo treatment include polycythemia, seizures, hypertension, stroke, myocardial infarction, congestive heart failure, tumor progression, and shortened time to death. None of these adverse effects have been reported in Epo-treated neonates in more than 3000 patients enrolled in randomized controlled trials (Juul, 2012; Wang et al., 2015;

Natalucci et al., 2016). Epo trials in term and preterm neonates for the purposes of testing its erythropoietic effect have shown it to be a safe drug for use in this population. In particular, an increased risk of retinopathy of prematurity for preterm infants treated with Epo has not been substantiated in prospective randomized controlled trials (Ohlsson and Aher, 2014; Fauchère et al., 2015; Ohls et al., 2015). Accumulating data using neuroprotective doses (1000–3000 U/kg per dose) also demonstrate safety (Fauchère et al., 2015). A Cochrane review of Epo neuroprotection of preterm infants concluded that there is long-term neurodevelopmental benefit from early Epo use, with no increase in morbidity (Wang et al., 2015).

The Preterm Erythropoietin Neuroprotection Trial (PENUT; IND 12656, [ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01378273) NCT01378273) is a phase III randomized, placebo-controlled, double-blind study of Epo neuroprotection in infants born between 24 and 28 weeks' gestation. Nine hundred and forty patients will be enrolled at multiple sites across the United States and will be evaluated at 22–26 months' corrected age. Enrolled patients will receive the study drug from less than 24 hours of age to 32 completed weeks' postmenstrual age. This study is adequately powered to provide definitive results regarding the neuroprotective potential of Epo in this population. The primary outcome is death or severe NDI at 22–26 months' corrected age, with a secondary outcome of death, severe NDI, or moderate NDI. Patients will be evaluated by the third edition of the Bayley Scales of Infant and Toddler Development and a standardized neurologic examination. Results should be available in 2018 (Juul et al., 2015).

Future Outlook on Neuroprotection for Preterm Brain Injury

There are three concepts we would like to bring to the reader's attention that we believe are likely to inform the next generation of therapies moving into clinical trials. These are applicable to both term and preterm infants: cell-specific targeting, harnessing endogenous protection (specifically, regulating microglial phenotype), and tertiary-phase injury processes. In addition, for infants born preterm, the concept of paucity of protectors, unblocking the maturation blockade of oligodendrocytes, and normalizing changes to the gray matter must be addressed.

Cell-Specific Targeting

Improvements in techniques for separating cells into pure populations have fostered cell type–specific analyses in injury models to understand injury and repair (Williamson et al., 2011; Smith et al., 2014; Schang et al., 2014b). These studies have revealed that the same pathway can participate in opposing ways during normal development or during injury in adjacent cell types. A striking example of this is found in the Wnt pathway. Specifically, decreasing Wnt pathway signaling is crucial for normal oligodendrocyte maturation, with increased signaling noted in oligodendrocytes in areas of white matter injury (Fancy et al., 2009). In contrast, in microglia, high Wnt pathway activity is required to prevent these innate immune cells from becoming activated to a proinflammatory, oligodendrocyte-damaging phenotype (Van Steenwinckel et al., 2016). This cell specificity can be harnessed by targeting nanoparticles to facilitate the cell-specific delivery of neurotherapeutics (Kannan et al., 2014). One of the first and most robust examples of this approach was the use of a polyamidoamine dendrimer to deliver *N*-acetyl-D-cysteine to reduce brain injury in a rabbit model

of CP (Kannan et al., 2012). The dose of *N*-acetyl-D-cysteine required for equivalent neuroprotection was reduced 10-fold by use of cell-targeting technology when compared with intraperitoneal injection.

Microglial Activation States

Our understanding of the importance of neuroinflammation in almost every kind of brain injury and disease has lead to an explosion of research into the activation state of microglia (Vexler et al., 2006; Ziebell and Morganti-Kossmann, 2010; Drake et al., 2011; Hagberg et al., 2012; Heneka et al., 2015). Microglia are unique yolk sac–derived resident innate immune cells of the brain with self-renewing potential and numerous critical roles in normal brain development and injury (Ransohoff and Perry, 2009; Hart et al., 2012; Tay et al., 2016). The activation state of microglia is dependent on extracellular cues, and they can morph into phenotypes that when simplified can be described as proinflammatory M1–like, immunoregulatory M2a–like, and antiinflammatory M2b–like (Chhor et al., 2013). This understanding that microglia can be protective or regenerative (Kitamura et al., 2009; Hamelin et al., 2016) is further complicated by observations that these functions are temporally and spatially regulated in an injury-specific or disease-specific manner (Hart et al., 2012; Hu et al., 2012; Wang et al., 2013). This increasingly nuanced understanding of how microglia participate in injury and normal development (Schmid et al., 2009; Nagamoto-Combs and Combs, 2010; Tarassishin et al., 2011; Butovsky et al., 2014; Tang et al., 2014) means that the route of administration and the timing must be considered when one is attempting to modulate microglial function to maximize the protective/regenerative effectiveness of microglia (Hickman et al., 2008; Hu et al., 2012). This growing knowledge of microglial biology will be further facilitated by the aforementioned cell isolation techniques. Infusions of microglia or their bone marrow–derived myeloid cell “cousins” monocytes and macrophages are starting to be considered as potential therapies for brain injury because of their similarities to stem cells, including the secretion of trophic factors, migratory ability, and their long life span (Cartier et al., 2014). Infusions of these cells, either genetically or chemically prepolarized to a repair-regenerate phenotype, are neuroprotective in models of multiple sclerosis (Takahashi et al., 2007; Mikita et al., 2011; Beutner et al., 2013).

Tertiary-Phase Injury Processes

There is increasing clinical and experimental evidence to support the presence of persistent, active mechanisms that prevent regeneration and/or exacerbate brain damage following perinatal brain injury (Dammann, 2007; Fleiss and Gressens, 2012); these mechanisms are termed *tertiary-phase injury processes*. Most notably, it appears that neuroinflammatory processes persist, including microglial activation (Bilbo et al., 2008; Van Steenwinckel et al., 2013). From a clinical perspective, therapies that can be applied long after injury to improve neurologic condition are highly appealing. Together with improved understanding of cell specificity and repair-regenerative microglial phenotypes, research into tertiary-phase injury will hopefully unlock the potential for neurologic improvements for the many hundreds of thousands of people with perinatally acquired brain injury. Early clinical trials using stem cells to treat perinatal brain injury have targeted the tertiary phase (patients 1–12 years of age) because of safety issues of treating patients in the acute phase. The potential for pharmacologic therapies to improve outcomes when they are administered

weeks or months after injury is being demonstrated in animal models (Saraceno et al., 2010; Zhang et al., 2011; Byrnes et al., 2012).

Paucity of Endogenous Protectors

The fetus is supplied via the placenta with many factors, including progesterone, melatonin, thyroid hormones, and estrogen. A lack of these factors because of early birth is hypothesized to contribute to NDI in preterm infants and may be an exacerbating factor in injury to term infants (Dammann and Leviton, 1999; Dammann and O'Shea, 2008; Hirst et al., 2008). Each of these substances has been shown to be neuroprotective in animal models of perinatal injury (Gibson et al., 2008; Brown et al., 2009; Schang et al., 2014b). The hypothesis of a paucity of neuroprotectors is several decades old, and clinical trials for several of the prime candidates have produced negative or inconclusive findings (Schang et al., 2014a; Schuit et al., 2015; Norman et al., 2016). However, it is hoped that other endogenous protectors may also have potential, such as neuregulins (Dammann et al., 2008; Taveggia et al., 2008), allopregnanolone (Yawno et al., 2007; Fleiss et al., 2012), and esterol (Trajkovic et al., 2006).

Targeting Oligodendrocyte Maturation

As the quality of obstetric care has improved, the pathophysiology of injury to infants born preterm has changed. After preterm birth, it is known that oligodendrocytes are a cell type that is particularly vulnerable to injury, particularly between 22 and 32 weeks' gestation. However, it is not the death of oligodendrocytes but a maturation blockade that is responsible for the characteristic hypomyelination observed in these infants (Billiards et al., 2008; Favrais et al., 2011; Verney et al., 2012; Schang et al., 2014a). Stimulating maturation of oligodendrocytes is also an avenue of therapeutic design for multiple sclerosis (Franklin and Kotter, 2008; Fancy et al., 2010). In multiple sclerosis lesions, oligodendrocytes proliferate locally and then mature in a relapsing and remitting progression. Over time it is the failure of oligodendrocyte maturation and remyelination that leads to the accumulation of lesions that impair function. It is unknown if therapies "borrowed" from the field of multiple sclerosis, where oligodendrocytes proliferate in the context of injury and then fail to mature, will be beneficial to preterm infants with encephalopathy of prematurity, where oligodendrocytes born in the normal developmental milieu undergo developmental arrest (Franklin and Ffrench-Constant, 2008; Fancy et al., 2011a). Drugs designed for treatment of multiple sclerosis that target oligodendrocyte maturation that may also benefit infants with perinatal injury include XAV939, rapamycin, olesoxime, benztropine, and activin A (Fancy et al., 2009; Fancy et al., 2011b; Miron et al., 2013; Kremer et al., 2015).

Targeting Gray Matter Damage

Encephalopathy of prematurity has historically been considered a white matter injury, but the changing spectrum of injury has allowed us to identify subtle changes in gray matter (Boardman et al., 2006; Ball et al., 2011, 2013; Zubiaurre-Elorza et al., 2011). The exact nature of gray matter changes is still not fully understood but appears to involve changes in interneuron number and/or distribution (Salmaso et al., 2014) and changes in synapse density

(Dean et al., 2011a, 2011b; McClendon et al., 2014). There are no drugs to our knowledge to directly target these processes, only attempts to normalize factors leading to preterm birth and downstream neuroinflammatory processes.

Current Therapies for Term Infants

Therapeutic Hypothermia

Therapeutic hypothermia (TH) (72 hours of cooling to $33.5 \pm 0.5^\circ\text{C}$ followed by slow rewarming, 0.5°C per hour to normothermia) is now the standard of care to treat neonates with moderate-to-severe hypoxic-ischemic encephalopathy (HIE). Numerous randomized controlled trials have investigated the benefit of therapeutic hypothermia for improving outcomes of newborns with HIE, and multiple metaanalyses are available for review.

A Cochrane metaanalysis by Jacobs et al. (2013) included 11 randomized controlled trials, comprising 1505 term and late preterm infants with moderate-to-severe HIE. This review concluded that TH resulted in less death and better neurodevelopmental outcomes for survivors. Eight of the 11 studies (1344 infants) demonstrated that TH decreased the combined outcome of death or major neurodevelopmental disability at 18 months of age (46%, 312/678, vs. 61%, 409/666, in controls) (typical relative risk [RR] 0.75, 95% confidence interval [CI] 0.68–0.83; typical risk difference [RD] -0.15 , 95% CI -0.20 to -0.10). The number needed to treat to benefit one newborn is 7 (95% CI 5–10).

Secondary outcomes of the Cochrane review included mortality, major neurodevelopmental disability, adverse effects of cooling, and additional indicators of neurodevelopmental outcome (e.g., severity of EEG abnormality, seizures, MRI findings). Eleven studies (1468 infants) supported decreased mortality with TH (25%, 186/736, vs 34%, 250/732, in controls, RR 0.75, 95% CI 0.64–0.88), for a number needed to treat of 11. Eight studies (917 infants) demonstrated that TH decreases neurodevelopmental disability in surviving infants (26%, 130/495, vs 39%, 166/422, in controls, RR 0.77, 95% CI 0.63–0.94), for a number needed to treat of 8. On the basis of the available randomized controlled trials, TH appears to increase survival without increasing major disability in survivors.

Reported adverse effects of TH include sinus bradycardia, thrombocytopenia, fat necrosis, disseminated intravascular coagulopathy, and rarely pulmonary hypertension (Gunn et al., 1998; Eicher et al., 2005; Gluckman et al., 2005; Shankaran et al., 2005; Azzopardi et al., 2009; Simbruner et al., 2010; Zhou et al., 2010; Jacobs et al., 2011). TH has not been associated with a significant increase in the rates of major cardiac arrhythmia and hypotension or in the need for inotropic agents.

Long-term outcome data are currently available from 379 of the 1505 infants (25.2%) included in the Cochrane metaanalysis. One hundred and nine of 208 (91.3%) participants in the US National Institute of Child Health and Human Development study were assessed at the ages of 6–7 years (Shankaran et al., 2012). The primary outcome of death or an intelligence quotient (IQ) below 70 remained lower in the TH group (46 of 97 children, 47%) than in the control group (58 of 93 children, 62%) but was no longer significant (RR in the TH group 0.78, 95% CI 0.61–1.01). The death rate remained significantly lower in the TH group (28% vs 44% of controls, $P = .04$) as did the rate of death or severe disability (41% vs 60% of controls, $P = .03$). There was no

significant difference in the rates of moderate or severe disability (35% of the TH group vs 38% of controls, $P = .87$) or CP (17% of the TH group vs 29% of controls, $P = .14$). On the basis of this study, it appears TH increases survival without increasing the rates of major disability, an IQ score below 70, or cerebral palsy in surviving children.

One hundred and twenty-seven of 325 infants (39%) enrolled in the European Total Body Hypothermia for Neonatal Encephalopathy (TOBY) trial were assessed at 6–7 years of age. At 18 months, children in the TOBY trial who had received TH had reduced risks of cerebral palsy and better Mental Developmental Index and Psychomotor Developmental Index scores based on the Bayley Scales of Infant and Toddler Development, second edition (Azzopardi et al., 2009). At 6–7 years of age children who had received TH (75 of 145, 52%) had significantly higher survival with an IQ of 85 or higher compared with children not treated with TH (52 of 132, 39%, RR 1.31, $P = .04$) (Azzopardi et al., 2014). While the percentages of children who died in the TH group (29%) and the control group (30%) were similar, in survivors, normal neurologic outcomes were more common in the TH group (65 of 145, 45%) than in the control group (37 of 132, 28%); RR 1.60. The risk of CP was significantly lower in surviving children from the TH group (21%) than in surviving children from the control group (36%). Children from the TH group also had less moderate or severe disability (22%) than children from the control group (37%).

Follow-up of children from the Cool Cap trial also demonstrated that 18-month neurodevelopmental assessments are predictive of long-term functional outcomes. Guillet et al. (2012) reported outcomes on 62 (32 cooled, 30 controls) of 135 (46%) surviving 7–8-year-old children enrolled in the Cool Cap trial. With use of a WeeFIM instrument to qualitatively measure self-care, mobility, and cognitive function, disability status at 18 months was strongly associated with WeeFIM ratings at 7–8 years of age ($P < .001$), supporting a sustained treatment effect of TH for neonatal encephalopathy. Unfortunately, this follow-up study had insufficient power to determine whether treatment with TH affected long-term outcome.

Cooling Duration and Depth

Even when treated with TH, close to 50% of neonates with moderate-to-severe HIE die or experience significant NDI. In an attempt to optimize this therapy, a clinical trial was conducted to determine whether a longer duration of TH or cooling to a lower temperature might show further benefit (Shankaran et al., 2014). The trial was stopped with only 364 neonates enrolled (of 726 planned) because of safety and futility concerns. Analysis of the predefined secondary outcomes, safety and neonatal intensive care unit (NICU) deaths, was done by marginal comparisons of 72 hours' versus 120 hours' duration and 33.5°C versus 32.0°C (predefined secondary outcomes). Both longer and deeper cooling were associated with increased mortality. Death rates increased from 7% (7 of 95 neonates) to 16% (15 of 96 neonates) when cooling at 33.5°C was extended from 72 to 120 hours. Similarly, death rates increased from 14% (13 of 90 neonates) to 17% (14 of 83 neonates) when cooling at 32°C was extended from 72 hours to 120 hours. The adjusted RR for NICU deaths for the 120-hour group versus the 72-hour group was 1.37 (95% CI 0.92–2.04) and for the 32.0°C group versus the 33.5°C group was 1.24 (95% CI 0.69–2.25). Future analyses will determine the primary outcome of death or disability at 18–22 months.

Therapies on the Horizon for Term Infants

Adjunctive Neuroprotective Treatments Plus Therapeutic Hypothermia

Erythropoietin

As noted earlier, Epo is a glycoprotein originally identified for its role in erythropoiesis but which has remarkable neuroprotective and reparative effects in the central nervous system (reviewed in Rangarajan and Juul, 2014; Juul and Pet, 2015). In the setting of hypoxia–ischemia, Epo receptor expression is rapidly upregulated (Sola et al., 2005; Jantzie et al., 2013). If Epo is available to bind to the upregulated receptor, cell survival is promoted, but in the absence of Epo, the pathway of programmed cell death predominates (Jantzie et al., 2013, 2015). This creates an important rationale for exogenous Epo administration, given that upregulation of Epo may take several hours, whereas brain injury can occur after brief but catastrophic insults that are insufficient to stimulate an increase in endogenous Epo synthesis (Traudt et al., 2013).

Preclinical studies of Epo neuroprotection following hypoxic–ischemic brain injury show robust histologic and functional benefit (Kumral et al., 2004; Achterberg et al., 2005; Chang et al., 2005; Demers et al., 2005; Gonzalez et al., 2007; McPherson et al., 2007; Iwai et al., 2010; Sargin et al., 2010; Pet and Juul, 2014; Rangarajan and Juul, 2014; Juul and Pet, 2015). Epo has both early and late beneficial effects. Early benefits include antiapoptotic and antiinflammatory effects (Digicaylioglu and Lipton, 2001; Sun et al., 2005; Kellert et al., 2007; Juul et al., 2009; Xiong et al., 2011), while later effects include increased neurogenesis, plasticity, and tissue remodeling after hypoxia–ischemia (Iwai et al., 2007; Ransome and Turnley, 2007; Yang et al., 2007; Wang et al., 2008; Reitmeir et al., 2011). In nonhuman primates, Epo reduces the combined outcome of death or CP and improves neurologic function in animals undergoing hyperthermia therapy for HIE (Traudt et al., 2013). Phase I and phase II clinical trials have raised no safety concerns and suggest that infants with HIE treated with multiple doses of Epo during the first week of life have better neurologic outcomes (Zhu et al., 2009; Elmahdy et al., 2010). The Neonatal Erythropoietin in Asphyxiated Term Newborns (NEAT) and Neonatal Erythropoietin And Therapeutic Hypothermia Outcomes in Newborn Brain Injury (NEATO) trials have demonstrated safety, feasibility (Wu et al., 2012), and beneficial outcomes as measured by early MRI, biomarkers, and 6-month and 2-year outcomes (even among infants with significant brain injury seen on MRI) (Rogers et al., 2014; Wu et al., 2016). Epo is commercially available and safe in infants. Phase III trials are now in the early stages of execution internationally, including the Preventing Adverse Outcomes of Neonatal Hypoxic Ischaemic Encephalopathy with Erythropoietin trial (Australia) and the High-Dose Erythropoietin for Asphyxia and Encephalopathy trial (United States).

Xenon

Xenon, a noble gas that crosses the placenta and the blood–brain barrier, binds to *N*-methyl-D-aspartate glutamate receptors to inhibit function, thus decreasing neuronal apoptosis (Franks et al., 1998; Ma et al., 2007). Significant benefit was demonstrated in preclinical studies of HIE (Lobo et al., 2013), so the multicenter Total Body Hypothermia Plus Xenon (TOBY-Xe) trial was conducted in the United Kingdom. Ninety-two infants (36–43 weeks) were enrolled, 46 of whom were randomly assigned to cooling only, and 46 were randomly assigned to xenon treatment plus cooling (Azzopardi et al., 2015). The primary outcomes were assessment of reduced thalamic lactate to *N*-acetylaspartate ratios measured with magnetic

resonance spectroscopy and preserved fractional anisotropy in the posterior limb of the internal capsule determined by MRI within 15 days of birth. Lactate to *N*-acetylaspartate ratios have been demonstrated to be a good predictive imaging biomarker of neurodevelopmental outcomes (Thayyil et al., 2010). Changes in fractional anisotropy, a measure of brain connectivity derived from the diffusion tensor imaging that assesses the degree of regional anisotropic diffusion, correlate well with subsequent outcomes in neonates with HIE (Tusor et al., 2012). The TOBY-Xe trial was underpowered to detect changes in the lactate to *N*-acetylaspartate ratios but adequately powered to detect changes in fractional anisotropy. Although no serious adverse events were recorded, no significant magnetic resonance differences were detected between groups. On the basis of the magnetic resonance results of 37 infants in the cooling-only group and 41 in the cooling plus xenon group, early TH plus treatment with 30% xenon for 24 hours begun more than 6 hours after birth is not likely to improve clinical outcomes compared with TH alone for newborns with neonatal encephalopathy. Multiple factors that may impact inhaled xenon treatment outcomes, including the timing, dose, and duration of treatment, need further study. Study results of the CoolXenon3 Study (ClinicalTrials.gov NCT02071394) combining TH with 18 hours of xenon inhalation in cooled infants with HIE are pending.

Argon

In addition to xenon, another inert gas, argon, has shown promise as an adjunct to hypothermia in a piglet model of neonatal encephalopathy (Broad et al., 2016), building on a wealth of in vitro and small animal model of injury data supporting its neuroprotective qualities (Ulbrich and Goebel, 2015). Argon is more abundant than xenon and as such is cheaper and more practical to use clinically, not requiring a complex rebreathing/scavenger setup. As yet there are no clinical trials using argon to treat any neurologic injury.

Melatonin

Neuroprotective benefits of melatonin have been demonstrated in an HIE piglet model, in which intravenously administered melatonin plus TH significantly improved cerebral energy metabolism on the basis of proton magnetic resonance spectroscopy studies, reduced apoptosis in deep brain structures, and decreased microglial activation in the cortex at 48 hours after injury (Robertson et al., 2013). In uncooled term human newborns with neonatal encephalopathy ($n = 10$), oral melatonin (eight doses of 10 mg each separated by 2-hour intervals) administration within the first 6 hours after delivery reduced the serum malondialdehyde, a lipid peroxidation product, and nitrite/nitrate levels at 12 and 24 hours compared with those in untreated, uncooled controls ($n = 10$), suggesting a role for melatonin in reducing oxidative damage (Fulia et al., 2001). In a recent prospective trial by Aly et al. (2015) involving 45 term newborns, 30 with HIE and 15 healthy controls, compared with TH alone ($n = 15$), melatonin treatment (10 mg/kg daily for five enteral doses) plus TH ($n = 15$) was associated with decreased seizures per EEG and decreased white matter abnormalities on MRI after 2 weeks of age and improved survival without neurologic or developmental abnormalities at 6 months of age ($P < .001$).

Stem Cells

There have been several decades in which stem cells have promised to revolutionize the treatment of diseases, from Alzheimer disease to CP (Diukman and Golbus, 1992; van Bekkum, 1998; Mattson,

2000). In the field of perinatal brain injury, these hopes have been confounded by research issues that include a lack of consistent use of cell type (caused by no thorough comparison of cell types ever being made), no standardization for the preparation of cells, and issues in interpreting species-specific effects of cells. There is still a great deal that needs to be understood in the field; for a comprehensive review, see Fleiss et al. (2014). Despite these unresolved questions there are several ongoing clinical trials (Table 62.1). Of the trials thus far completed, only one robustly designed study (double blind, randomized, and placebo controlled) has reported outcomes (Min et al., 2013). This study combined Epo treatment and umbilical cord blood therapy and reported improvements in motor and functional scores at 6 months of age for combined Epo treatment and umbilical cord blood therapy compared with Epo treatment only and no treatment. This study was small (30 patients per arm) and did not have an umbilical cord blood-only group. No effect of Epo was observed, and the study authors suggest the main treatment effect was due to umbilical cord blood treatment, not Epo. In addition, only patients in whom stem cells had been administered were treated with the immunosuppressant cyclosporine. Given the importance of persisting inflammation in the neuropathologic processes of CP (see Tertiary Phase Injury Processes; Fleiss and Gressens, 2012), this is an important confounder. Several additional trials with robust design are under way.

The following sections describe the main cell types proposed for neurotherapeutic use and provide information on the ongoing clinical trials in the field of perinatal brain injury. The great majority of clinical trials are performed with umbilical cord blood–derived stem cells or bone marrow–derived stem cells (Table 62.1).

Umbilical Cord Stem Cells. Umbilical cord blood contains various stem cell populations, including mesenchymal stem cells (see later), endothelial progenitor cells, and umbilical cord blood mononuclear cells (UCB-MNCs). UCB-MNCs differentiate in vitro into virtually all types of mature cell, including neural cells. Mononuclear cells (MNCs) are also found in Wharton jelly, and together with UCB-MNCs these MNCs have a greater proliferative potential than MNCs derived from the bone marrow. The accessibility, low antigenicity, and absence of ethical issues for cell harvesting make these cells attractive therapeutic options.

Mesenchymal Stem Cells. Mesenchymal stem cells (MSCs) can be derived from fetal and adult tissues, including first-trimester fetal blood, liver and bone marrow, placenta, adult bone marrow, and umbilical cord blood. MSCs can differentiate into all forms of mesenchymal tissue (e.g., bone, cartilage, fat) and neurons, although MSCs derived from fetal sources retain a greater potential for plasticity compared with adult-derived MSCs. The attributes of MSCs that make them attractive therapeutics include their low immunogenicity, as they do not express major histocompatibility complex class II, and their antiinflammatory and immunosuppressive properties.

Embryonic Stem Cells. Embryonic stem cells (ESCs) are derived from the inner mass of the blastocyst and can self-renew indefinitely, being able to maintain an identical phenotype following cell division. ESCs are pluripotent (able to generate cells from the ectoderm, mesoderm, and endoderm) and represent an almost unlimited supply of cells for transplant. However, there are concerns about teratoma formation after transplant, as they are obviously not autologous, and their use has considerable ethical concerns.

Induced Pluripotent Stem Cells. Induced pluripotent stem cells (iPSCs) are created by causing terminally differentiated somatic cells to revert to pluripotency by chemical or genetic reprogramming.

TABLE 62.1 Clinical Trials Using Stem Cell Therapy in Patients Following Perinatal Brain Injury

| Title | Trial Duration | Intervention | Age at Inclusion | Enrollment |
|--|------------------------|---|-----------------------|-----------------|
| A Safety and Feasibility Study of Autologous Cord Blood and Human Placental Derived Stem Cells in Neonates With Severe Hypoxic-Ischemic Encephalopathy | Jan. 2016 to Jun. 2019 | Autologous human placental-derived stem cells administered in conjunction with autologous cord blood in neonates with severe hypoxic-ischemic encephalopathy (diagnosed as per standard hypothermia inclusion criteria). Safety only | Less than 6 h | 20 (estimated) |
| Efficacy of Stem Cell Transplantation Compared to Rehabilitation Treatment of Children With Cerebral Palsy (Palsy) | Oct. 2013 to Dec. 2015 | Mesenchymal stem cells derived from umbilical cord, four doses versus rehabilitation only versus no therapy no rehabilitation controls | 1–14 years | 300 (estimated) |
| Is Autologous Umbilical Cord Blood Reinfusion Beneficial in Children With Cerebral Palsy: A Randomized, Blinded, Placebo-Controlled, Crossover Study | Jun. 2010 to Jul. 2016 | Two injections, one of autologous human cord blood–derived stem cells and one vehicle control administered 12 months apart. Randomization of order of injections. Two-year follow-up | 12 months to 6 years | 120 |
| Evaluation the Side Effects of Bone Marrow Derived CD133 Cells Transplantation in Cerebral Palsy Patients | Oct. 2011 to May 2012 | Intrathecal injection of bone marrow–derived CD133 cells. Safety only | 4–12 years | 12 |
| The Safety of Multiple Intrathecal Injection of Bone Marrow Derived CD133 Cells in Patients With Cerebral Palsy | Apr. 2012 to Apr. 2014 | Intrathecal injection of bone marrow–derived CD133 cells versus patients not receiving stem cells | 4–12 years | 8 |
| Effects of the Infusion of Autologous Noncryopreserved CD34+ Cells in Newborns With Asphyxia | Jan. 2012 to Apr. 2013 | Intravenous infusion of autologous stem cells within the first 48 h after birth versus control group of patients who meet the inclusion criteria (Apgar score 0–3 at 1 min, metabolic acidosis, hypoxia, multiple organ failure) but who do not wish to have the intervention | 37–42 weeks | 20 |
| Safety and Efficacy of Bone Marrow MNC for the Treatment of Cerebral Palsy in Subjects Below 15 Years | Mar. 2011 to Aug. 2014 | Intrathecal injection of 1 million autologous mononuclear cells | 3–15 years | 100 (estimated) |
| Allogeneic Umbilical Cord Blood and Erythropoietin Combination Therapy for Cerebral Palsy | May 2010 to Apr. 2011 | Allogeneic umbilical cord blood infusion under nonmyeloablative immunosuppression, plus erythropoietin twice weekly for 4 weeks (two initial doses of 500 IU/kg intravenously, followed by six doses of 250 IU/kg subcutaneously) and rehabilitation versus erythropoietin plus rehabilitation versus rehabilitation only | 10 months to 10 years | 105 |
| Safety and Effectiveness of Cord Blood Stem Cell Infusion for The Treatment of Cerebral Palsy in Children | Jan. 2010 to Feb. 2014 | Mononuclear cell–enriched cord blood unit prepared for infusion versus placebo | 1–12 years | 20 |
| Intrathecal Autologous Stem Cells for Children With Hypoxic/Ischemic Brain Injury | Jul. 2009 to Apr. 2010 | Patients will be stimulated with granulocyte colony stimulating factor five times, then bone marrow will be harvested and patients will be later infused with 8–10 mL of stem cells (CD34 ⁺) by the intrathecal route versus baseline motor scores | 1–8 years | 18 |

BBS, Berg Balance Scale; DTI, diffusion tensor imaging; ¹⁸F-FDG PET, [¹⁸F] fluorodeoxyglucose positron emission tomography; IQ, intelligence quotient; MNC, mononuclear cells; MRI, magnetic resonance imaging.

| Status | Study Design | Outcome Measures | Sponsor and Trial Identifier |
|-------------------------------------|--|--|--|
| Not yet recruiting | End point classification: safety Intervention model: single group assignment Masking: open label Primary purpose: treatment | Primary: infusion reaction within 30 days Secondary: neurologic improvement (MRI, DTI, and Sarnat testing) | New York Medical College, United States NCT02434965 |
| Ongoing | Allocation: randomized End point classification: safety/efficacy Intervention model: parallel assignment Masking: single blind (outcomes assessor) Primary purpose: treatment | Primary: Gross Motor Function Measure-88 and Gross Motor Function Measure-66 at 12 months Secondary: biochemical analysis of glutamic species at 12 months | General Hospital of Chinese Armed Police Forces NCT01929434 |
| Completed and results pending | Allocation: randomized End point classification: efficacy Intervention model: crossover assignment Masking: double blind (subject, caregiver, investigator, outcomes assessor) Primary purpose: treatment | Primary: standardized measures of neurodevelopmental function at 2 years Secondary: at 2 years, (1) quality of life, (2) MRI changes, (3) blood transcriptomics | Duke University Medical Center, United States NCT01147653 |
| Completed (Zali et al., 2015) | End point classification: safety Intervention model: single group assignment Masking: open label Primary purpose: treatment | Primary: infusion reaction within 30 days Secondary: neurologic scores (speech and motion) | Royan Institute, Iran NCT01404663 |
| Ongoing | Allocation: randomized End point classification: safety/efficacy Intervention model: parallel assignment Masking: open label Primary purpose: treatment | Primary: infusion reaction within 48 hours and motor and sensory score at six months Secondary: neurologic score (Gross Motor Function Measure-66), balance (BBS), and incidence of spasm | Royan Institute, Iran NCT01763255 |
| Completed and results not available | Allocation: nonrandomized End point classification: safety/efficacy Intervention model: parallel assignment Masking: open label Primary purpose: prevention | Primary: Amiel-Tison neurologic assessment at 1 week and 1 year | Hospital Universitario Gonzalez Monterrey, Mexico NCT01506258 |
| Ongoing | End point classification: safety/efficacy Intervention model: single group assignment Masking: open label | Primary: at 6 months, Ashworth scale and overall motor control using Oxford scale Secondary: at 6 months, IQ using Binet-Kamat scale, social behavior testing, and reduction in deformity | Chaitanya Hospital, Pune, India NCT01832454 |
| Completed (Min et al., 2013) | Allocation: randomized End point classification: safety/efficacy Intervention model: parallel assignment Masking: double blind (subject, caregiver, investigator, outcomes assessor) Primary purpose: treatment | Primary: Gross Motor Performance Measure at 1, 3, and 6 months compared with the baseline Secondary: Korean version of Bayley Scales of Infant Development-II Mental Scales, Quality of Upper Extremity Skills Test, and Pediatric Evaluation of Disability Inventory at 0, 1, 3, and 6 months. Brain glucose metabolism using ¹⁸ F-FDG PET at 2 weeks. MRI at 6 months. Adverse reactions by 6 months | Sung Kwang Medical Foundation, South Korea NCT01193660 |
| Ongoing | Allocation: randomized End point classification: safety/efficacy Intervention model: crossover assignment Masking: double blind (subject, caregiver, investigator, outcomes assessor) Primary purpose: treatment | Primary: safety via repeated follow-up over 1 year with clinical and laboratory evaluations Secondary: standardized Gross Motor Function Measure evaluation | Georgia Regents University, United States NCT01072370 |
| Completed (Mancia-Gueria, 2014) | End point classification: efficacy Intervention model: single group assignment Masking: open label Primary purpose: treatment | Primary: Battelle Developmental Inventory at 30 days Secondary: Battelle Developmental Inventory at 180 days | Hospital Universitario Gonzalez Monterrey, Mexico NCT01019733 |

Reprogramming techniques were initially limited to genetic manipulations using integrating viruses. Newer techniques using chemical reprogramming are a significant improvement as it is thought that these cells will have a reduced risk of aberrant proliferative ability after transplant. A benefit of these iPSCs is autologous transfer, but reprogramming rates are low, and great technical skills are required.

Neural Stem Cells. Neural stem cells (NSCs) are derived from the embryonic or fetal brain but are also found in the adult subventricular zone and dentate gyrus. NSCs can be derived from iPSC to overcome issues related to nonautologous transplants. NSCs can differentiate into neurons, oligodendrocytes, and astrocytes, but the same risk of teratoma formation exists for NSC as ESC and iPSCs.

Amniotic Fluid–Derived Stem Cells. Amniotic fluid contains stem cells with a phenotypic profile between that of ESCs and that of MSCs. Amniotic fluid–derived stem cells are multipotent and nontumorigenic. They need to be harvested by amniocentesis, limiting their use.

Clinical Management Strategies

Along with seizures, neonates with neonatal encephalopathy frequently demonstrate cardiovascular instability evidenced by hypotension, metabolic acidosis, and pulmonary hypertension. Unlike the more standardized TH guidelines, clinical approaches regarding antiepileptic use, fluid resuscitation, pressor support (including hydrocortisone treatment), the use of base replacement (e.g., sodium bicarbonate), ventilation strategies, oxygen saturation targets, inhaled nitric oxide use, and blood transfusion parameters may all influence outcomes in the setting of TH.

The use of medications to provide sedation and prevent shivering in cooled newborns with neonatal encephalopathy must also be further studied. The current use of morphine during TH is not evidence based and may not be ideal because of its side effect profile (e.g., respiratory depression, urinary retention, constipation) and because it does not specifically prevent shivering. Dexmedetomidine (DEX) and clonidine, both α_2 -adrenergic receptor agonists, are promising alternative sedatives because they specifically prevent shivering without suppressing respirations. DEX reduces inflammation (Taniguchi et al., 2008; Yang et al., 2008), does not produce abnormal brain histologic features (neonatal rats) (McAdams et al., 2015), and produces neuroprotection in animal models of HIE (Laudenbach et al., 2002; Paris et al., 2006; Sato et al., 2010). Currently, trials to assess the pharmacokinetics and safety of DEX (Cool DEX study, NCT02529202) and clonidine (NCT02252848) in newborns with neonatal encephalopathy during TH are under way.

Future Outlook on Term Brain Injury Neuroprotection

As highlighted in the initial sections of this chapter, cell death plays a significant role in brain injury in the term infant, and as such, more therapies are specifically tailored to target these processes. The research areas discussed in the following sections have not yet been studied in clinical trials for perinatal brain injury but may be of future use following validation in this population.

Remote Ischemic Postconditioning

Remote ischemic postconditioning is a promising therapeutic intervention whereby brief episodes of ischemia/reperfusion of a

limb abrogate damage in another organ (such as the brain) that has experienced hypoxia–ischemia. Remote ischemic postconditioning has been shown to protect the adult and neonatal brain in rodent models of hypoxia–ischemia when applied immediately at reperfusion or delayed by up to 24 hours (Drunalini Perera et al., 2014) and when applied immediately in a piglet model of neonatal encephalopathy induced with hypoxia–ischemia (Ezzati et al., 2016). The molecular mechanism of action underpinning protection by remote ischemic postconditioning is still under debate but likely involves soluble factors released from the postconditioned tissues. There are 12 registered clinical trials (ClinicalTrials.gov; limb+ischemic+postconditioning) in adults using a modified cuff, on the arm akin to the cuffs used for blood pressure measurement, for indications including liver and heart transplants and stroke. However, in the piglet model, inguinal cuffs to occlude the femoral artery of both legs were necessary, and issues need to be overcome for the design, manufacture, and training in the use of such equipment in a clinical setting for perinatal brain injury.

Targeting Inflammation

Extensive preclinical and clinical data suggest that the presence of inflammation sensitizes the term brain to injury leading to neonatal encephalopathy (Fleiss et al., 2015). Marked improvements in obstetric care have reduced the burden of neonatal encephalopathy in term infants, but the rate remains at 8.5 per 1000, and the standard therapy of hypothermia reduces poor outcome in only one-eighth of infants. Stratification of patients by inflammatory status is increasingly considered a potential way to identify responders/nonresponders to hypothermia and/or as a key to identify patients who might benefit from alternative therapies. Increasing interest in biomarker discovery (Beckstrom et al., 2011; Blaise, 2013) and our burgeoning ability to implement crib side testing will facilitate patient stratification for this. No specific differences in the inflammatory response of term infants that would necessitate specific antiinflammatory agents to be designed have been identified, but this is an understudied area. More than likely, we will witness the repurposing of inflammatory therapies, especially in concert with cell-specific delivery to reduce off-target toxic effects of drugs that have failed in traditional testing.

Targeting Autophagy

Autophagy is the orderly recycling of intracellular components and is critical for normal cellular function. In times of injury or stress, autophagy can be protective, by providing alternative sources of energy and by eliminating toxins or pathogens, but it can also promote cell death (for an extensive review, see Descloux et al., 2015). As such, understanding and modulating autophagy are avenues of interest for neurotherapeutic design. There is a lack of specific pharmacologic tools to modulate autophagy, but genetic studies in mice have proven the neuroprotective capacity of modulating autophagy (Koike et al., 2008; Ginot et al., 2014), including in the immature brain (Xie et al., 2016). Furthermore, the levels of markers for autophagy are increased in human postmortem analysis of both injured premature brains (Vontell et al., 2015) and injured term brains (Descloux et al., 2015). Of particular interest is basic research into mitophagy, recycling of mitochondria, as mitochondrial dysfunction is a keystone of cell death in perinatal brain injury (Hagberg et al., 2014; Thornton and Hagberg, 2015). Ideal neuroprotection will likely include multiple targeted approaches at different times.

Neonatal Neuroimaging

JEFFREY J. NEIL AND TERRIE E. INDER

KEY POINTS

- Cranial ultrasonography is useful for evaluating ventricular size and hemorrhage in preterm neonates during their neonatal intensive care unit (NICU) stay.
- Magnetic resonance imaging (MRI) is the most sensitive imaging modality for many of the forms of injury found in both term and preterm neonates, including watershed injury, basal ganglia injury, white matter injury, and stroke.
- Computed tomography (CT) should only be used when MRI is not available.
- The MRI findings following brain injury are dynamic, with diffusion imaging being most sensitive 2–4 days after injury, and T₁-weighted and T₂-weighted imaging being most sensitive thereafter.
- Neuroimaging studies of both term and preterm neonates have prognostic value.

CONTROVERSY BOX

Is Brain Magnetic Resonance Imaging Near Term Equivalent Age Helpful in Extremely Preterm Babies?

Pros: An MRI study obtained near the time of hospital discharge (term equivalent age) has better predictive value for subsequent neurodevelopmental outcome than any other clinical or imaging metric, particularly when systematic MRI scoring systems are employed. The use of MRI to help identify those infants at high risk for neurodevelopmental impairment may allow targeting of therapy services to those infants who would benefit most from them, and early initiation of appropriate therapy services may improve outcomes. MRI at term may also be used as a quality neurologic outcome metric for brain injury that is difficult to detect on ultrasound, such as white matter and cerebellar injury, and brain growth measures, thereby allowing the neonatal unit to track the true incidences of injury and impaired brain growth in their patient population.

Cons: There are no studies proving that obtaining an MRI at the time of hospital discharge in very preterm infants leads to improved neurodevelopmental outcomes. Furthermore, the imprecise relationship between MRI findings and outcome may cause uncertainty in prognosis, leading to increased anxiety for parents.

Additional comments: Discussing long-term prognosis for very preterm infants with their parents prior to discharge from the NICU should be standard practice. This discussion should be informed by clinical markers such as gestational age, clinical history, and neurologic examination as well as MRI (when appropriate). We suggest that term MRI studies be obtained on those infants at highest risk for adverse outcome based on gestational age and/or clinical course. In this context, it is important that clinicians be trained in the relationship between gestational age, clinical course, MRI, and outcome. Concerns regarding parental anxiety are based on anecdotal evidence but highlight the importance of the nature of this communication to empower and enable families rather than cause concern.

In this chapter, we focus primarily on the three main techniques for assessing brain structure and injury in infants—cranial ultrasonography (CUS), computed tomography (CT), and magnetic resonance imaging (MRI). We review the fundamentals of the methods and describe their application to the preterm and term-born populations. We also review methods that are under development and may prove clinically useful in the future.

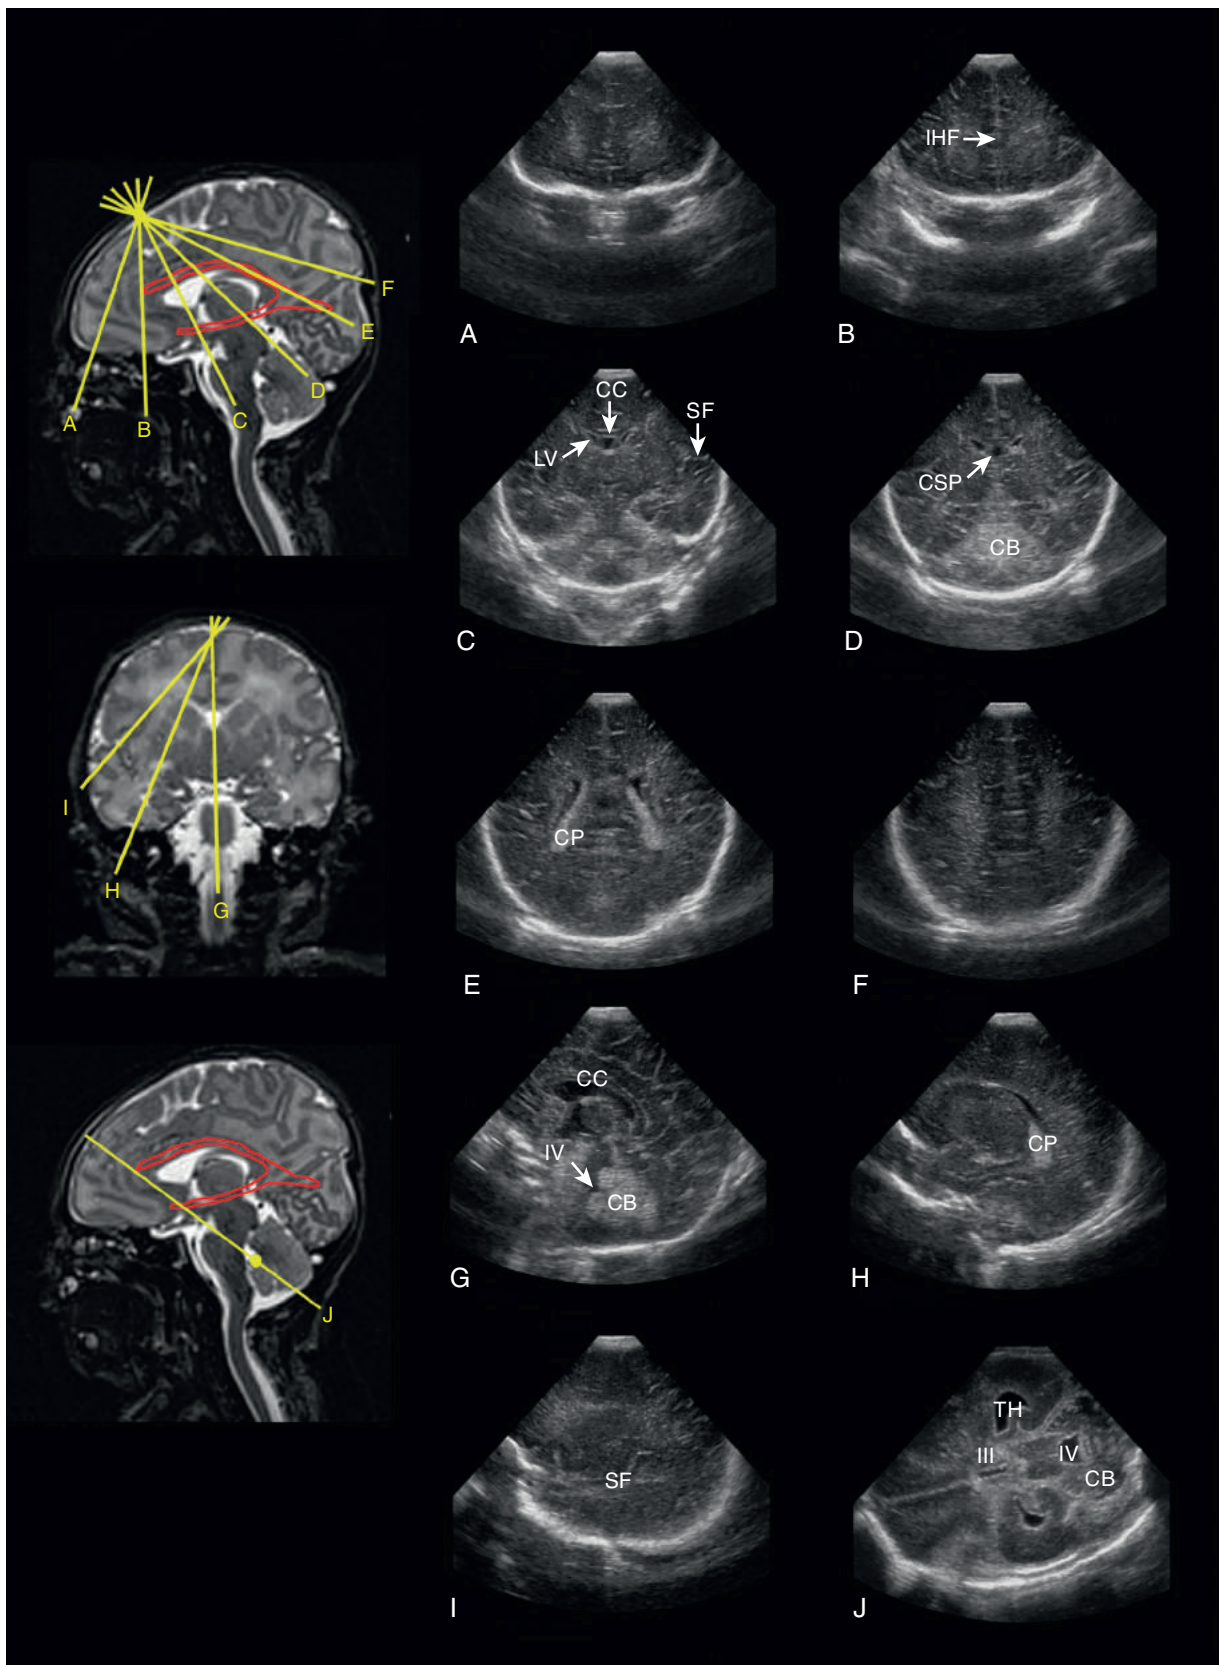

Imaging Modalities

Cranial Ultrasonography

CUS is based on the reflection of ultrasound from tissue. Since ultrasound does not penetrate bone well, CUS is limited to infants with open fontanels (though ultrasound can sometimes be obtained through the squamous portion of the temporal bone). CUS studies are mainly done through the anterior fontanel, often with inclusion of images of the posterior fossa taken through the mastoid foramen (Fig. 63.1). Since image quality falls off with distance from the ultrasound probe, images of the posterior fossa obtained through the mastoid foramen have richer detail than those obtained through the anterior fontanel. Image quality also worsens somewhat as the fontanels gradually close, and obtaining CUS images of the brain is no longer feasible once the fontanel closes completely at the approximate age of 6 months.

Tissue interfaces, such as that between cerebrospinal fluid (CSF) and brain parenchyma, give a strong echo return. Consequently, CUS excels at providing an outline of the ventricular system. Hemorrhage is also readily visible and appears bright because of the strong echo from the loosely packed red blood cells. This combination of properties makes CUS very useful for evaluating posthemorrhagic hydrocephalus as well as cystic changes in the periventricular white matter in preterm neonates (vide infra). In comparison, the echo return from brain parenchyma is considerably smaller, with parenchyma appearing relatively dark compared with hemorrhage or the ventricular outline. Furthermore, there is little contrast between injured and uninjured tissue. As a result, areas of *nonhemorrhagic* brain injury, such as stroke, are difficult to detect with CUS, though areas of nonhemorrhagic injury may sometimes appear brighter than surrounding tissue.

It is important that clinicians caring for preterm neonates personally review the images from every CUS study on their patients, just as neonatologists look at every chest X-ray and neurologists every MRI study. One potential hurdle to learning to evaluate CUS studies is its unique imaging planes. A standard CUS image set obtained through the anterior fontanel typically starts with

• **Fig. 63.1** Head Ultrasound Studies and Their Corresponding Imaging Planes. The imaging planes (yellow) are shown on a midline sagittal magnetic resonance image upon which an outline of a lateral ventricle is drawn in red. (A–I) The ultrasound images were taken through the anterior fontanel. (J) The image was taken through the mastoid foramen. CB, Cerebellum; CC, corpus callosum; CP, choroid plexus; CSP, cavum septum pellucidum; III, third ventricle; IV, fourth ventricle; IHF, interhemispheric fissure; LV, lateral ventricles; SF, Sylvian fissure; TH, temporal horn of the lateral ventricle.

slices that are very close to coronal in the anterior part of the brain, with the images becoming progressively more oblique, and closer to axial, for images from the posterior parts of the brain (see Fig. 63.1A–F). Images are then obtained with the ultrasound probe oriented to obtain a sagittal midline image (see Fig. 63.1G), as well as parasagittal images of the hemispheres and lateral ventricles (see Fig. 63.1H–I). Images obtained through the mastoid window are also oblique and may extend superiorly/anteriorly to include the third ventricle in very preterm neonates, for whom the mastoid window is still wide open (see Fig. 63.1J). Another effect of the necessity of imaging around rather than through bone is that the cerebral convexities cannot be seen using CUS.

In addition to structural information, ultrasound also has the capacity to provide measurements related to blood flow. This ability results because the frequency of the ultrasound signal used for imaging undergoes a Doppler shift when reflected by moving structures such as the cells in flowing blood. Thus Doppler ultrasonography has proven useful for evaluating the patency of both arteries and veins. This Doppler shift is readily converted to units of velocity (m/s), but deriving a blood flow value (mL/min per g of tissue) from a velocity value is not straightforward, as factors such as the diameter of the vessel, laminar blood flow, and the angle of the ultrasound beam relative to the blood vessel must be taken into account. In practice, the Doppler measurements are usually expressed as the resistive index, which is a unitless number calculated as the difference between systolic and diastolic flow velocities divided by the systolic flow velocity. Notably, resistive index is not affected by changes in the angle of the probe relative to the blood vessel. A related index is the pulsatility index, which is calculated in the same fashion as the resistive index except that the denominator is the mean flow velocity rather than systolic flow velocity. These measurements are typically taken from the anterior cerebral artery as it wraps around the genu of the corpus callosum and/or the middle cerebral artery as it turns in a superior–inferior direction. These vessel segments are chosen because the beam from the ultrasound probe, positioned at the anterior fontanel, is parallel to the arteries at these points, providing more consistent measurements. A comparison of CUS with other imaging modalities is provided in Table 63.1.

Computed Tomography

CT scanning has been used to study infants since its invention in the 1970s and was the imaging modality used 40 years ago to

develop the Papile classification of intracranial hemorrhage for preterm neonates (Papile et al., 1978). It is similar to CUS in that it excels at showing hemorrhage and the ventricular outline. In addition, like CUS, it does not provide particularly good tissue contrast for nonhemorrhagic injury. However, unlike CUS, it provides a clear view of the cerebral convexities. It provides a reasonable view of the posterior fossa, but image quality in this area is often degraded by the effects of surrounding bone. CT scanning is falling out of favor as an imaging modality for infants because of concerns regarding its use of ionizing radiation. In the rapidly developing brain, irradiation may cause injury that affects subsequent IQ (Ron et al., 1982; Hall et al., 2004). Furthermore, there is concern about an increased incidence of subsequent head and neck cancers (Karlsson et al., 1998; Brenner et al., 2003; Boice, 2015; Krille et al., 2015).

Magnetic Resonance Imaging

In comparison with CUS, MRI has the disadvantage that infants must be moved from the intensive care unit to the radiology department for study, though this may change as MR scanning systems that are suitable for housing within the neonatal intensive care unit (NICU) are developed. Furthermore, the infant is relatively inaccessible while in the MRI scanner in the event of a medical emergency. The major advantage of MRI relative to CUS and CT is that it provides unmatched structural detail, high sensitivity to parenchymal injury, and high sensitivity to brain malformations (Raybaud et al., 1996; Cowan et al., 2005; de Vries and Volpe, 2013). From a practical standpoint, imaging infants requires adaptations of the scanning process. For example, optimum signal-to-noise ratio, and hence better image quality, is achieved when the radiofrequency coil used for imaging is size-matched to the infant head, although it remains common practice to use a head coil designed for adult imaging for imaging infants. In addition, image contrast is different for newborns as compared with older children (see below) so that pulse sequence timing parameters must be optimized for the infant brain to obtain images with optimum contrast-to-noise ratio. Finally, infants are considerably less cooperative in holding still during the scanning process than older patients. As a result, it is standard practice in some centers to sedate infants to minimize movement. However, a variety of approaches have been developed to mitigate subject motion (Glover and Pauly, 1992; Pipe, 1999; Mathur et al., 2008; Tamhane and Arfanakis, 2009; Olesen et al., 2010; Gholipour et al., 2011; Tisdall et al., 2012; Ooi et al., 2013; Gumus et al., 2015). Thus sedation

TABLE 63.1 Comparison of Imaging Modalities

| Modality | Advantages | Disadvantages |
|----------------------------------|---|---|
| Cranial ultrasound (CUS) | <ul style="list-style-type: none"> • Bedside test • Inexpensive • Excellent for evaluating ventricular size and hemorrhage • Provides an indication of vessel patency (Doppler) | <ul style="list-style-type: none"> • Unable to image cerebral convexities • Challenging for nonradiologist to interpret • Poor tissue contrast for nonhemorrhagic injury • Misses subtle brain malformations such as heterotopias |
| Computed tomography (CT) | <ul style="list-style-type: none"> • Readily available in most medical centers • Relatively inexpensive • Shows hemorrhage and the ventricular outline well | <ul style="list-style-type: none"> • Uses ionizing radiation • Poor tissue contrast for nonhemorrhagic injury • Requires the infant to be transported to the scanner |
| Magnetic resonance imaging (MRI) | <ul style="list-style-type: none"> • Offers a rich variety of contrast types (structural and functional) • Provides unparalleled image detail • Shows parenchymal injury well • Shows malformations and heterotopias well | <ul style="list-style-type: none"> • Expensive • Requires the infant to be transported to the scanner. • It can be challenging to monitor infants while in the scanner. • Scan times are longer than for CT or CUS. |

for scanning should no longer be standard practice, though may still be necessary in some cases.

T₁-Weighted and T₂-Weighted Imaging

MRI differs from CUS and CT in that it offers a wide variety of contrast types. Most MRI is based on the detection of signal from the hydrogen nuclei of water ($^1\text{H}_2\text{O}$), which are present at a concentration of approximately 110 mol/L in tissue. For “conventional” (T_1 -weighted and T_2 -weighted) imaging, image contrast is based on the T_1 or T_2 relaxation time constants of water ^1H . These time constants vary with the local chemical environment. For example, ^1H in CSF water has a relatively large T_2 time constant, and hence CSF appears bright on T_2 -weighted images compared with other tissues.

White matter contrast on MRI studies changes dramatically between birth and 1 year of life. Unmyelinated white matter appears dark on T_1 -weighted images and bright on T_2 -weighted images. With myelination, the T_1 and T_2 time constants change such that myelinated white matter has the opposite signal properties—bright on T_1 -weighted images and dark on T_2 -weighted images. This change in contrast can be employed to detect myelination (Ganzetti et al., 2014), which takes place at different rates in different brain areas. For example, primary motor cortex and visual cortex develop earlier than most other brain areas, and this corresponds to the relatively early myelination of their associated white matter tracts. In a term-born neonate, the myelinated corticospinal tract and optic radiations appear bright on T_1 -weighted images against a background of darker-appearing, unmyelinated white matter (Fig. 63.2). Since the majority of white matter in newborns is unmyelinated, and the signal characteristics of gray matter do not change appreciably during development, gray–white contrast is inverted in neonates compared with older infants and children. As myelination proceeds, white matter signal intensity gradually changes (Almli et al., 2007). Between the ages of 6 and 9 months, white and gray matter signal intensities are similar on both T_1 -weighted and T_2 -weighted images, making it difficult to obtain good gray–white image contrast (see Fig. 63.2). Thus while MRI may still be useful in patients at this age, it is not particularly sensitive for detecting subtle cortical malformations and heterotopias. By the age of 1 year, gray–white contrast is fully inverted and is similar to that of older children and adults.

One final consideration for T_1 -weighted and T_2 -weighted imaging is the detection of hemorrhage. While both CT and CUS also detect hemorrhage, MRI can provide both an indication of the age of the injury (Table 63.2) and the presence of associated nonhemorrhagic parenchymal injury. MR angiography can also sometimes be used to identify associated vascular occlusion. A detailed description of

the clinical use of MRI for detection of hemorrhage is provided near the end of this chapter.

Diffusion Imaging

The contrast in diffusion images is based on water motion, with water displacements on the order of 2–10 μm being measured. The method was originally used for measuring diffusion in liquids and was subsequently adapted to MRI in the mid-1980s (LeBihan et al., 1986). When the method is applied to tissue, the parameter describing water displacements is referred to as the *apparent* diffusion coefficient (ADC, with units of mm^2/s) in recognition of the fact that water motion in tissue is influenced by a variety of factors in addition to Brownian motion, such as active transport and barriers to water movement. Diffusion imaging quickly became a mainstay of clinical imaging when it was discovered that it provides an early marker of stroke (Moseley et al., 1990). It is now known that diffusion images are sensitive to brain injury because water ADC values decrease within minutes following a variety of injuries in addition to stroke, including seizure (Zhong et al., 1993, 1995; Righini et al., 1994; Prichard et al., 1995), spreading depression (Latour et al., 1994; Busch et al., 1995; Rother et al., 1996; Takano et al., 1996), excitotoxic injury (Benveniste et al., 1992; Verheul et al., 1993), and trauma (Ford et al., 1994).

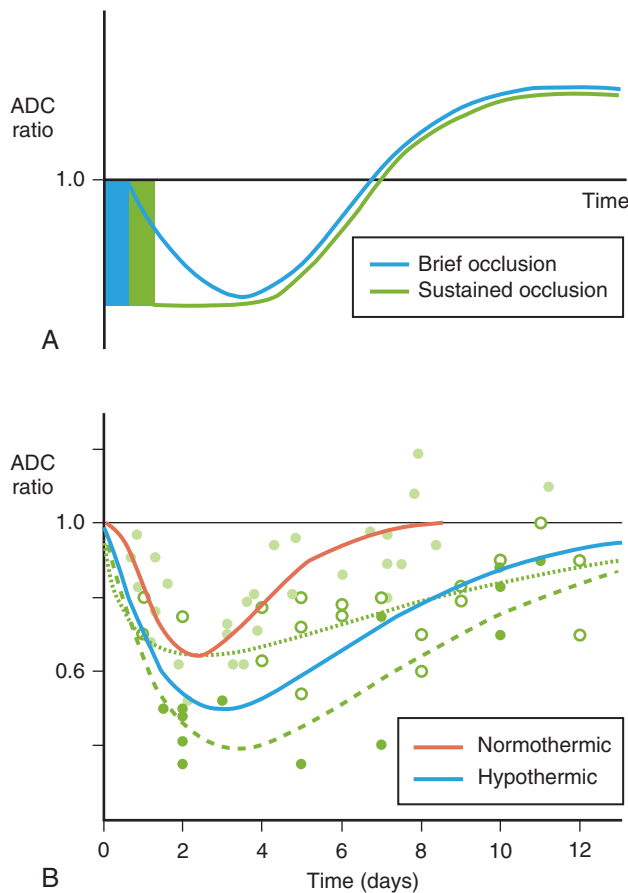

The ADC changes following injury are dynamic, both on a time scale of hours and a time scale of days. In rodent studies (Li et al., 2000), water ADC values in an area of stroke fall within minutes of occlusion of the middle cerebral artery. If the occlusion is maintained for 90 minutes or more, the ADC values remain low for 3–4 days and then gradually rise to greater than normal values by 5–6 days (Fig. 63.3A). This process is known as *pseudonormalization* because ADC values pass through normal 4–6 days after injury. Notably, the time course of ADC changes is different for briefer injury. If blood flow is restored after 30 minutes of occlusion, ADC values return to normal within minutes of restoring blood flow (see Fig. 63.3A). This is followed by a secondary ADC decline within the first 24 hours and a subsequent increase with pseudonormalization at 4–6 days. It has been suggested that this short-term return of ADC values to normal followed by a secondary decline may be related to secondary energy failure, but this has not been proven. However, this more complex time course following briefer injury may explain the presence of “diffusion negative” injury. In adults with stroke, diffusion MRI within the first day shows nearly all strokes, failing to show the injury in only approximately 6% of cases (Oppenheim et al., 2000). The failures may be due to a small fraction of stroke patients in whom blood flow spontaneously returns shortly after injury. In term-born infants, the incidence of diffusion negative injury is higher, perhaps on the order of 30% (McKinstry et al., 2002b). This is probably related to the different mechanism of injury in this population. One can imagine a neonate in utero who undergoes a period of hypoxic–ischemic injury (e.g., caused by placental abruption). This period of injury may be relatively brief if the neonate is rescued by being delivered and resuscitated. In this case, ADC values in injured tissue may transiently return to normal before undergoing a secondary decline followed by pseudonormalization. For neonates with somewhat longer injury, there is no short-term return of ADC values to normal. ADC values are low at delivery and stay low until pseudonormalization takes place. The time course of ADC changes in term-born neonates with injury is shown in Fig. 63.3B. Note also that ADC values tend to fall lower and for longer in neonates treated with therapeutic hypothermia (Bednarek et al., 2012). Overall, diffusion imaging is most sensitive to injury

TABLE 63.2 Magnetic Resonance Imaging Signal Changes After Parenchymal Hemorrhage

| Age of Hemorrhage | SIGNAL INTENSITY | |
|----------------------|------------------|-----------------|
| | T_1 -Weighted | T_2 -Weighted |
| 1–3 days | Isointense | Low |
| 3–10 days | High | Low |
| 10–21 days | High | High |
| 3–6 weeks | High | High |
| 6 weeks to 10 months | Isointense | Low |

• **Fig. 63.2** Sagittal (Left Column) and Axial (Right Column) Images From Subjects at Varying Ages. The images in the first row are from a newborn. Note that myelination of the corticospinal tract is visible at this age as an increase in signal intensity on the T₁-weighted image (*white arrow*). The images in the second row are from an 8-month-old child. Note the relatively poor gray-white contrast at this age as the signal intensity of white matter changes with myelination changes. Myelination of the optic radiations is visible on the T₂-weighted image as reduced signal intensity (*black arrows*). The images in the bottom row are from a 14-month-old child. Note that gray-white contrast is now fully reversed as a result of myelination.

• **Fig. 63.3** Time Course of Apparent Diffusion Coefficient Change Following Brain Injury. (A) The time course of apparent diffusion coefficient (ADC) change following brain injury. Blue represents 30-minute occlusion. Green represents 90-minute occlusion. The data are a composite from animal studies. (B) The time course of ADC change following brain injury in term-born human neonates. Red represents normothermic neonates. Blue shows neonates treated with therapeutic hypothermia. ADC ratios rather than absolute ADC values are used in the ordinate of both graphs because ADC values vary regionally in neonates and the areas of injury vary neonate to neonate. The ratio represents injured tissue over normal tissue, so values less than 1 indicate a reduction in ADC values. The dotted green line represents data from neonates treated with therapeutic hypothermia who had mild to moderate injury based on follow up MRI studies. The dashed green line represents data from those neonates with severe injury. ([A] Adapted from Kinstry RC, Miller JH, Snyder AZ, et al. A prospective, longitudinal diffusion tensor imaging study of brain injury in newborns. *Neurology*. 2002;59:824–833. [B] Adapted from Bednarek N, Mathur A, Inder T, Wilkinson J, Neil J, Shimony J. Impact of therapeutic hypothermia on MRI diffusion changes in neonatal encephalopathy. *Neurology*. 2012;78:1420–1427.)

2–4 days following injury but may show injury during the first day if the injury is severe. T_1 -weighted and T_2 -weighted imaging, on the other hand, usually show injury after 4–5 days. This timing should be taken into account when ordering/interpreting MRI studies to evaluate injury in neonates.

Another interesting aspect of diffusion is diffusion anisotropy. In white matter, water ADC values are greater parallel to axons than perpendicular to them. This is because water moving parallel to axons can move freely within myelin layers without crossing lipid membranes. Water moving perpendicular to axons must pass through myelin layers or go around them, which reduces their displacements.

This spatial variation in water ADC values is referred to as anisotropy, and diffusion for which ADC is the same in all directions is called isotropic. When diffusion images are obtained, diffusion is measured several times, along different axes, for each individual image slice. For each element, or voxel, in the image, these measurements can be combined to provide a spatial representation of water displacements. This representation can be expressed mathematically as a tensor, and hence the name “diffusion tensor imaging.” While these tensors can be displayed as ellipsoids (Neil, 2008), ellipsoid representations are cumbersome to use in clinical practice. As a result, summary parameters from these ellipsoids are shown (Fig. 63.4).

Measurement of diffusion anisotropy is applied most often to the evaluation of white matter. During development, anisotropy values increase dramatically with the addition of myelin (Huppi et al., 1998a; Neil et al., 1998), though unmyelinated white matter has a degree of diffusion anisotropy by virtue of the parallel arrangement of tubular axons. In many research studies, high anisotropy is associated with healthy white matter, and lower values are associated with injury or other abnormalities. Diffusion anisotropy measures can also be applied to gray matter. While cortical gray matter in adults has very low anisotropy values, this is not the case early in development, especially prior to term equivalent age. The developing cortical plate has a radial organization to its microstructure caused by the presence of radial glia and the apical dendrites of pyramidal cells (McKinstry et al., 2002a; Kroenke et al., 2005). This microstructure leads to high anisotropy values for the cortical plate for preterm infants in whom water ADC values are greater parallel to radial glia and apical dendrites than perpendicular to them. As the cortical plate matures, this radial organization is disrupted by the addition of basal dendrites to pyramidal cells, involution of radial glia, and myelination of intracortical white matter. As a result, anisotropy values fall steadily, reaching low values by term equivalent age and remaining low thereafter. Note that the pattern of anisotropy change over time is opposite for white and gray matter. Anisotropy values for the developing cortical plate are high and decrease as the cortex matures; anisotropy values for white matter initially are low and increase as white matter myelinates. The well-known regional variation in the rate of cortical development is also reflected in regional variation in the rate of change of cortical water anisotropy values (Kroenke et al., 2009).

While diffusion anisotropy is not commonly used in clinical practice, it can be helpful for white matter tractography (Basser et al., 2000). In this usage, the orientation of greatest water ADC values is determined for each white matter voxel. Since this is parallel to the direction of the axons in that voxel, this orientation can be used to follow fibers from voxel to voxel, thereby following a particular white matter tract (see Fig. 63.4D). This is starting to be used clinically for neurosurgical patients for whom identification of white matter tracts can help determine the optimum surgical approach (Potgieser et al., 2014).

Angiography

MR angiography is an important imaging modality for the evaluation of newborns. While a variety of approaches have been used to delineate vessels, contrast is usually based on macroscopic water motion. For example, it is possible to reduce the signal from static, extravascular water within an imaging slice so that the strongest remaining signal arises from intravascular water that flows into the slice during image acquisition. This can then be used to generate an angiogram. As noted below, angiography is particularly useful for assessing vascular occlusion in perinatal arterial stroke (Lequin et al., 2009) and for detecting sinovenous thrombosis (Berfelo et al., 2010).

• **Fig. 63.4** Diffusion Magnetic Resonance Imaging Data From Preterm (A–C) and Term (D) Neonates. (A) A diffusion map in which image intensity corresponds to water diffusion coefficient. (B) An anisotropy map in which image intensity corresponds to the degree of anisotropy. The *arrow* indicates an area of the developing cortical plate that has high anisotropy. The *arrowhead* indicates the genu of the corpus callosum. (C) A color map showing the preferred direction of water displacements: red = medial–lateral, green = anterior–posterior, and blue = superior–inferior. Note the medial–lateral crossing fibers of the corpus callosum (*arrowhead*) and superior–inferior corticospinal fibers of the posterior limb of the internal capsule (*arrow*). (D) Diffusion tractography of the corticospinal tracts (purple) in a term neonate.

Susceptibility-Weighted Imaging

Another form of contrast available in MR images is based on differences in local magnetic susceptibility and is sometimes known as T_2^* -weighted imaging. Susceptibility effects are caused by the juxtaposition of regions of different magnetic properties or susceptibilities. In the head, such areas are found at air–tissue

interfaces such as the sinuses, where they can cause unwanted image distortions, and near hemorrhages, where the reduced iron in deoxyhemoglobin produces strong susceptibility effects. Susceptibility-weighted images are extremely sensitive to hemorrhage, which appears dark (Fig. 63.5). Because magnetic field distortions caused by susceptibility effects extend beyond the susceptibility

• **Fig. 63.5** Axial, Susceptibility-Weighted Images From a Former Preterm Neonate. Note the areas of signal dropout caused by periventricular hemorrhage (arrows).

• **Fig. 63.6** ^1H Magnetic Resonance Spectra Obtained From a Human Brain at 3.0 Tesla. The spectrum on the left shows a relatively large lactate doublet in an asphyxiated term neonate. The spectrum on the right, obtained 9 days later, shows resolution of the lactate doublet and a reduction in the NAA resonance (arrow) relative to the choline and creatine resonances caused by neuronal loss. NAA, *N*-acetyl-containing compounds; ppm, parts per million.

boundary, small hemorrhages appear as relatively large areas of low signal on susceptibility-weighted images, making them very conspicuous and also making them appear larger than they actually are.

Magnetic Resonance Spectroscopy

As noted above, the concentration of water ^1H in brain is on the order of 110 mol/L, which provides abundant signal for the imaging modalities described above. MR spectroscopy involves the detection of ^1H in brain metabolites, such as lactate, which are present in concentrations on the order of 10^{-2} mol/L. This factor of 10^4

difference in concentration makes MR spectroscopy more challenging than conventional imaging. For example, it is not feasible to obtain a high-resolution image of brain lactate concentration. Instead, an MR spectrum is obtained from a single region of interest (single voxel spectroscopy), or a grid of spectra is obtained from a thick slice of brain (often known as chemical shift imaging). For typical ^1H spectroscopy in clinical use, the resonance peaks visible are choline, creatine, *N*-acetyl-containing compounds (NAA), and lactate (Fig. 63.6). The reasons that these resonances are more conspicuous than others are related to their chemistry and the fact that these metabolites are present in relatively higher concentrations.

Choline serves as a component of membranes and is also a constituent of the neurotransmitter acetylcholine. Creatine, when phosphorylated, stores energy in the form of phosphate bonds. (Phosphocreatine levels reflect the cellular energy state, but their detection requires phosphorous ^{31}P spectroscopy, as creatine and phosphocreatine are indistinguishable using ^1H spectroscopy.) The precise role of NAA in brain metabolism is unclear, but it is widely believed that NAA is found primarily in neurons and not glia, and a reduction in NAA level is often taken to reflect a reduction in the number of neurons present in a given region. Lactate is an intermediary of energy metabolism, and its levels may be increased under a variety of circumstances, including lack of oxygen and anaerobic glycolysis. Lactate levels may also be increased by the presence of inflammatory cells, which often utilize anaerobic glycolysis. Note that the ^1H signal from the methyl group of lactate is a doublet (a pair of peaks) because of its chemistry. In theory, it is possible to quantify metabolite levels (in mM) by comparing resonance amplitudes of metabolites with the water resonance amplitude in the same brain region. This quantitation is rarely employed in clinical practice, and resonance amplitudes are more often expressed as ratios. For example, the NAA/choline or NAA/creatine ratio may provide an estimate of the fraction of cells in a given area that are neurons. Finally, nuclei in addition to ^1H are detectable by MR spectroscopy. They include ^{31}P , sodium (^{23}Na), an isotope of carbon (^{13}C), and even the other two isotopes of hydrogen (^2H or nonradioactive deuterium and ^3H or radioactive tritium). While detection of these other nuclei is of significant scientific/research interest, particularly detection of hyperpolarized ^{13}C for noninvasive assessment of metabolism, non- ^1H spectroscopy has not yet found its way into clinical use.

Preterm Neonates

In recent decades, survival rates for very preterm neonates (born at less than 30 weeks' gestation) have improved dramatically due to advances in perinatal and neonatal care. In contrast to this improvement in mortality, long-term neurodevelopmental outcomes have not improved and remain problematic, with significant associated costs to individuals, families, and society (Anderson and Doyle, 2008; Hintz et al., 2011). In recent years, significant investigation has been undertaken to correlate perinatal, medical, and physical examination findings with long-term neurodevelopmental outcomes in an attempt to identify the neonates at greatest risk. High-grade brain injury (grade III or IV intraventricular hemorrhage [IVH], posthemorrhagic hydrocephalus, large cerebellar hemorrhage, and/or cystic periventricular leukomalacia [c-PVL]) is among the major risk factors for adverse neurodevelopmental outcome. This section will explore the neuroimaging characteristics of these forms of brain injury on CUS and MRI alongside a brief description of their neuropathologic characteristics.

Intraventricular Hemorrhage

Germinal matrix-IVH is the most common variety of neonatal intracranial hemorrhage and is characteristic of the preterm neonate. IVH has traditionally been graded as grade I–IV, as first reported by Papile and colleagues (Papile et al., 1978). This system is based on the presence and amount of blood in the germinal matrix and the lateral ventricles (Fig. 63.7). Grade I represents hemorrhage confined to the subependymal germinal matrix, grade II is hemorrhage within the lateral ventricles without ventricular dilatation, grade III is hemorrhage with ventricular dilatation and/or

hemorrhage occupying more than 50% of the ventricle, and grade IV requires parenchymal hemorrhage, typically abutting the superolateral aspect of the body and atrium of the lateral ventricle. Although grade IV IVH is now referred to as periventricular hemorrhagic infarction rather than IVH per se, most reports continue to classify the cranial ultrasound findings according to this earlier established classification system.

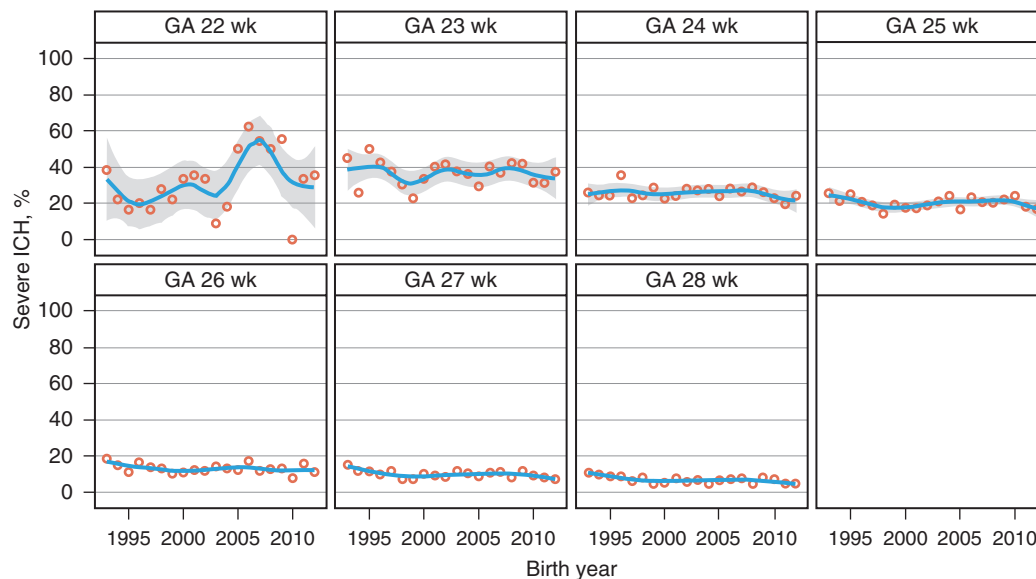

The incidence of IVH in preterm neonates remains high. Incidences derived from neonates studied in the late 1980s through the 2000s have documented that the incidence of IVH has remained unchanged at a level of approximately 25%. This is clearly documented in recent data summarizing the risk of IVH between 1993 and 2012 (Stoll et al., 2015). These data suggest that there may be a small decline in the risk of IVH for neonates with gestational ages of 26–28 weeks, with no change in the most immature neonates born at 22–25 weeks' gestation (Fig. 63.8). It has long been known that there is a higher risk for all forms of IVH in the most immature preterm neonates, with neonates less than 750 g having a risk of any IVH that is approximately threefold higher than for a preterm neonate over 1250 g (42% vs 14%) and a 10-fold higher risk of grade III–IV IVH (20% vs 2.1%) (Wilson-Costello et al., 2005). The other perinatal risk factors for IVH are summarized in Fig. 63.9.

CUS is the cornerstone of diagnosis for IVH in the preterm neonate and provides accurate and useful information for grading. At times, it may be difficult to distinguish a germinal matrix only (grade I) from a small intraventricular (grade II) IVH. Under these circumstances, a view of the lateral ventricles through the posterior fossa may be of assistance because blood tends to settle in the occipital horns of the lateral ventricles (neonates are usually lying face up during the CUS study), which are well seen with this view. MRI can also show the presence of IVH with similar accuracy, particularly in the acute phase, although it is not practical for serial examinations of preterm neonates. However, if MRI is first performed at term equivalent age, a small grade I hemorrhage may no longer be visible as a hemorrhage on conventional T_1 -weighted and T_2 -weighted images but may still be inferred from the presence of a germinal matrix cyst at the site of the original hemorrhage and/or an area of low signal intensity on susceptibility-weighted images reflecting remnants of blood products in the area.

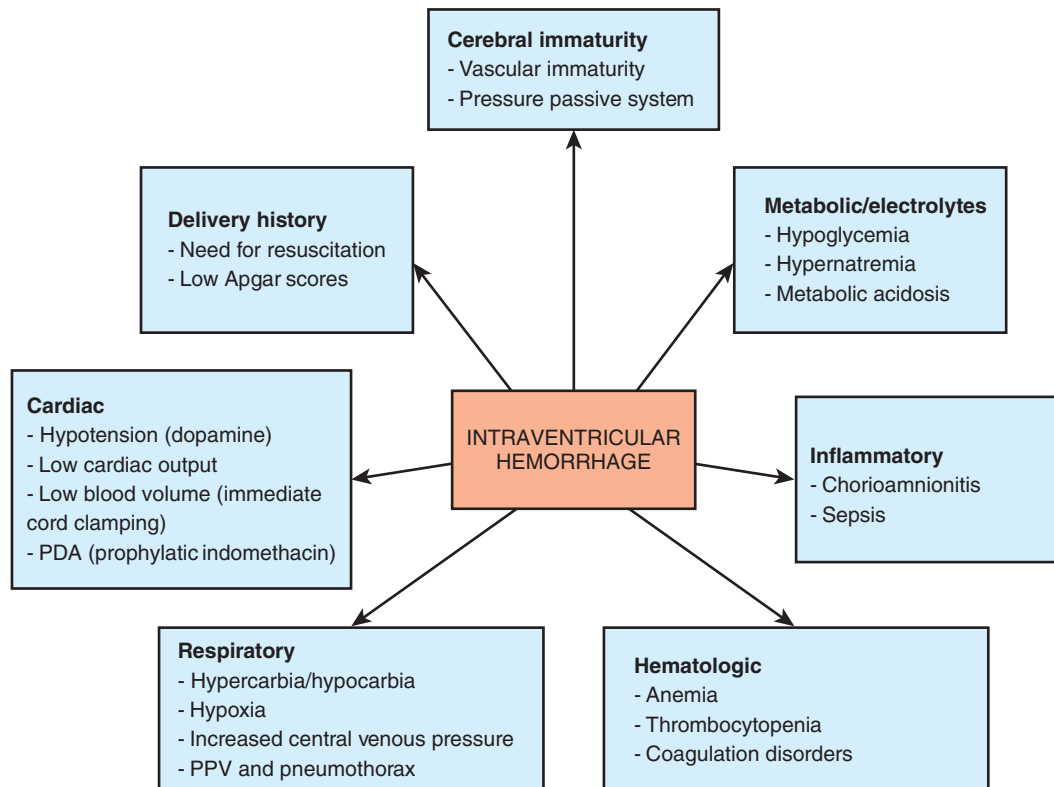

Information on the typical timing of IVH can inform the decision of when to undertake CUS in the preterm neonate early in the hospital course. In a cumulative series of 105 neonates with IVH studied by CUS from the first hours of life, approximately 50% had onset of hemorrhage on the first postnatal day, an additional 25% on the second day, and an additional 15% on the third day (Volpe, 2001). In a single study of 1105 neonates weighing 2000 g or less at birth, approximately 40% of the 265 who developed IVH did so within the first 5 hours of life (Paneth et al., 1993). The likelihood of onset of hemorrhage on the first postnatal day varied inversely with birth weight; in one series, 62% of hemorrhages in neonates between 500 g and 700 g birth weight occurred in the first 18 hours (Perlman and Volpe, 1986). In general, if screening were to be confined to a single postnatal day in the first days of life, a scan on the fourth postnatal day would be expected to detect approximately 90% of all hemorrhages. However, progression of the lesions occurs in approximately 20%–40% of the affected infants, with maximal extent of the lesion attained usually within 3–5 days of the initial diagnosis (Volpe, 2001). Thus a second scan after approximately 5 days is necessary to identify the maximal extent of hemorrhage.

• **Fig. 63.7** Grading of the Severity of Germinal Matrix–Intraventricular Hemorrhage on Coronal and Parasagittal Cranial Ultrasonography. (A) Grade I: germinal matrix hemorrhage. (B) Grade II: intraventricular hemorrhage (IVH) (filling < 50% of the ventricular volume). (C) Grade III: IVH with ventricular dilatation. (D) Grade V: large IVH with associated parenchymal echogenicity (hemorrhagic infarct). COR, Coronal; SAG RT, right parasagitta. (Courtesy of Walsh B, Inder T, Volpe JJ. IVH. • **Fig. 63.8** Severe Intracranial Hemorrhage by Birth Year and Gestation for Neonates Born at 22–28 Weeks' Gestation 1993–2012. Circles show the percentage of neonates born each year who were evaluated by cranial ultrasonography and diagnosed with grade III–IV intraventricular hemorrhage, a smoothed curve shows the trend, and shading indicates the 95% confidence interval for the curve. The year–gestational age interaction was significant ($P = .03$). Relative risks for the change per year were adjusted for study center, maternal race/ethnicity, neonate gestational age, small for gestational age, and sex. GA, Gestational age. (Data from Stoll BJ, Hansen NI, Bell EF, et al.; Eunice Kennedy Shriver National Institute of Child and Human Development Neonatal Research Network. Trends in care practices, morbidity, and mortality of extremely preterm neonates, 1993–2012. *JAMA*. 2015;314:1039–1051.)

• **Fig. 63.9** Risk Factors for Intraventricular Hemorrhage. PDA, Patent ductus arteriosus; PPV, positive pressure ventilation.

Approximately 30%–50% of neonates with a grade III–IV IVH develop posthemorrhagic ventricular dilatation (PHVD), and 20%–40% of neonates will consequently need a permanent ventriculoperitoneal shunt (Adams-Chapman et al., 2008; de Vries et al., 2013b). Thus preterm neonates with blood in the lateral ventricles (grade II–IV IVH) should be followed with serial CUS studies to monitor ventricular size. While qualitative evaluation of ventricular size can be useful, it is more informative to evaluate ventricular size in a quantitative fashion using established normative

values (Davies et al., 2000). Several quantitative measurements have been developed, including ventricular index, ventricular height, anterior horn width, and thalamo–occipital distance. No one measurement has proven to be superior to the others (Fig. 63.10) (Brouwer et al., 2010). However, the occipital horn area is the first and the frontal horn the last area to enlarge after IVH (Allan et al., 1982). Thus measurement of the thalamo–occipital dimension of the lateral ventricle (Brouwer et al., 2010) via the posterior fontanel is potentially the earliest indicator of ventriculomegaly.

• **Fig. 63.10** T₂-Weighted Coronal Magnetic Resonance Images From Three Preterm Neonates With a Periventricular Hemorrhagic Infarction. (A) A large periventricular hemorrhagic infarction (PVHI) is communicating with the lateral ventricle. (B) A smaller PVHI appears to be separate. (C) A small frontal PVHI without associated intraventricular hemorrhage. (Adapted from de Vries LS, Benders MJ, Groenendaal F. Progress in neonatal neurology with a focus on neuroimaging in the preterm infant. *Neuropediatrics*. 2015;46:234–241.)

At present, there are no standard recommendations for the frequency of CUS studies in this situation. Our practice has been to obtain CUS studies twice per week until ventricular size is stable for 1 week and then every 1–2 weeks thereafter.

In addition to helping identify infants in need of CSF drainage procedures, CUS is also useful for evaluating the effect of CSF drainage using preintervention and postintervention imaging and guiding the frequency and volume of CSF drainage necessary to reduce ventricular size. For example, when using lumbar puncture to treat ventriculomegaly infants with PHVD, the volume of CSF to drain varies greatly between infants (10 mL/kg is typical), with some infants requiring removal of large volumes of CSF to improve ventricular size (Hunt et al., 2003). In this case, CUS studies before and after the procedure give an indication of its effectiveness.

It is worth noting that the ventricular size at which to intervene with a CSF drainage procedure, as well as the drainage procedure to be used, remains an area of active research (Mazzola et al., 2014). Furthermore, the role of aggressive CSF drainage in improving outcomes remains unproven, although there are studies suggesting that more aggressive drainage may be helpful. For example, there are retrospective data suggesting that earlier intervention may be associated with a reduced need for a ventriculoperitoneal shunt and improved neurodevelopmental outcomes (de Vries et al., 2002; Brouwer et al., 2008). In addition, greater ventriculomegaly was associated with worse neurodevelopmental outcome in a study of 173 preterm neonates with grade III–IV IVH (Fig. 63.11) (Srinivasakumar et al., 2013). Overall, more data are needed to settle this issue. A multicenter randomized trial of early versus late ventricular intervention (ELVIS, number ISRCTN43171322, or ClinicalTrials.gov NCT00875758) has completed recruitment, and the results should shed further light on this question.

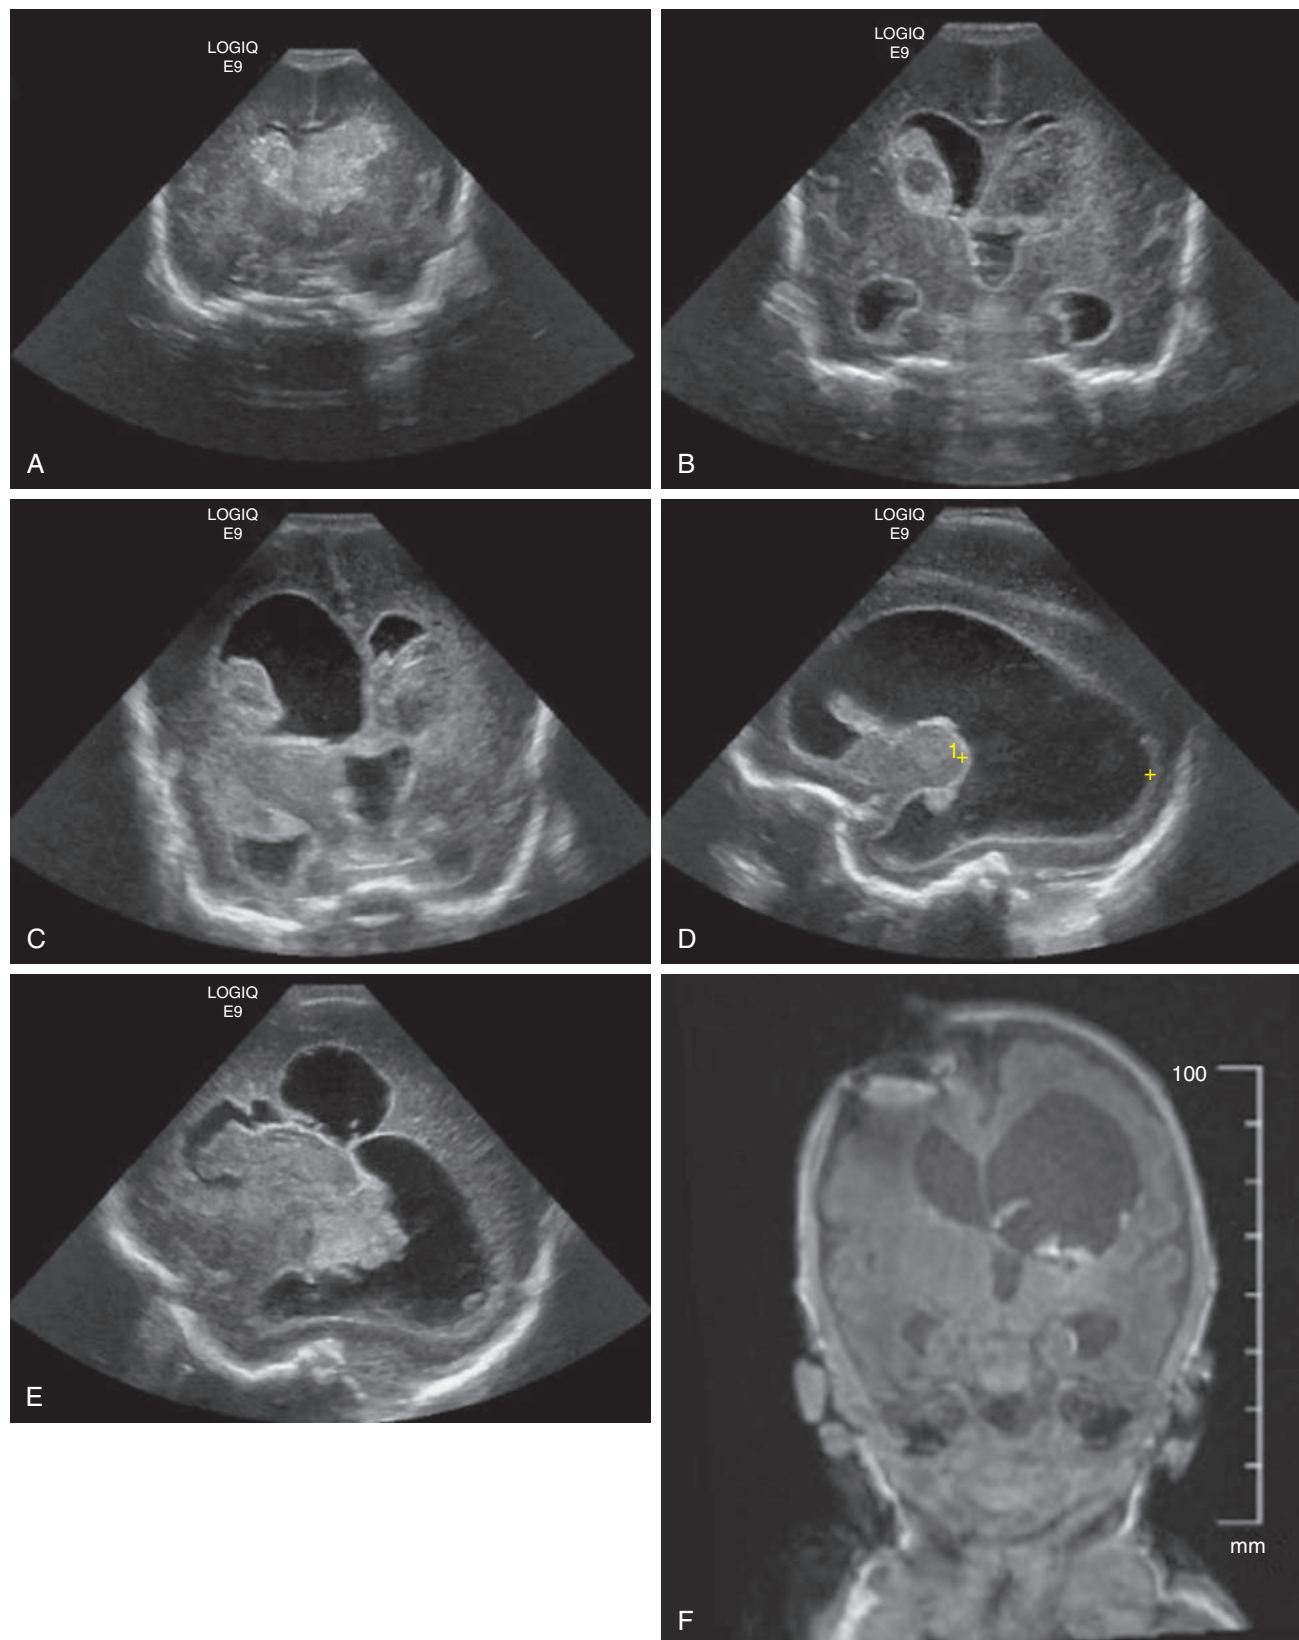

From a practical standpoint, it is important to make a clear clinical distinction between ventriculomegaly resulting from periventricular cerebral atrophy and ventriculomegaly resulting from hydrocephalus with attendant impairment of CSF dynamics for the formulation of appropriate management decisions. In general, the development of ventriculomegaly resulting from atrophy occurs slowly, over several weeks, and is not associated with the development of increased intracranial pressure (perhaps with a bulging fontanel) or rapid head growth and evolves to a state of stable ventricular size. In hydrocephalus, ventricular size may be unstable, decreasing if the condition is transient or increasing if the condition is progressive. The typical evolution of PHVD in a very preterm neonate (24 weeks' gestation) with grade IV IVH is shown in Fig. 63.12. Note the steady progression in ventricular dilatation, which is relieved by subgaleal shunt. The MRI at term equivalent demonstrates the asymmetry from left intraparenchymal volume loss and ex vacuo expansion.

The use of MRI to detect IVH early in the hospital course of a very preterm neonate is impractical for a variety of reasons, and there is no consensus regarding its use in this role. Nevertheless, MRI may be helpful for evaluating infants with PHVD by showing parenchymal details of periventricular hemorrhagic infarction that are useful for prediction of later neurodevelopmental outcome. Grade IV IVH can range from a small focal hemorrhage to an extensive hemorrhage involving most of both cerebral hemispheres (Jary et al., 2012). MRI can be used to more accurately determine the extent of a grade IV hemorrhagic lesion, which is a strong determinant of outcome (de Vries et al., 2015). With or without MRI, it is important for the clinician to appreciate the extent of a grade IV IVH (Fig. 63.13), ideally by reviewing the images, to accurately counsel the baby's family.

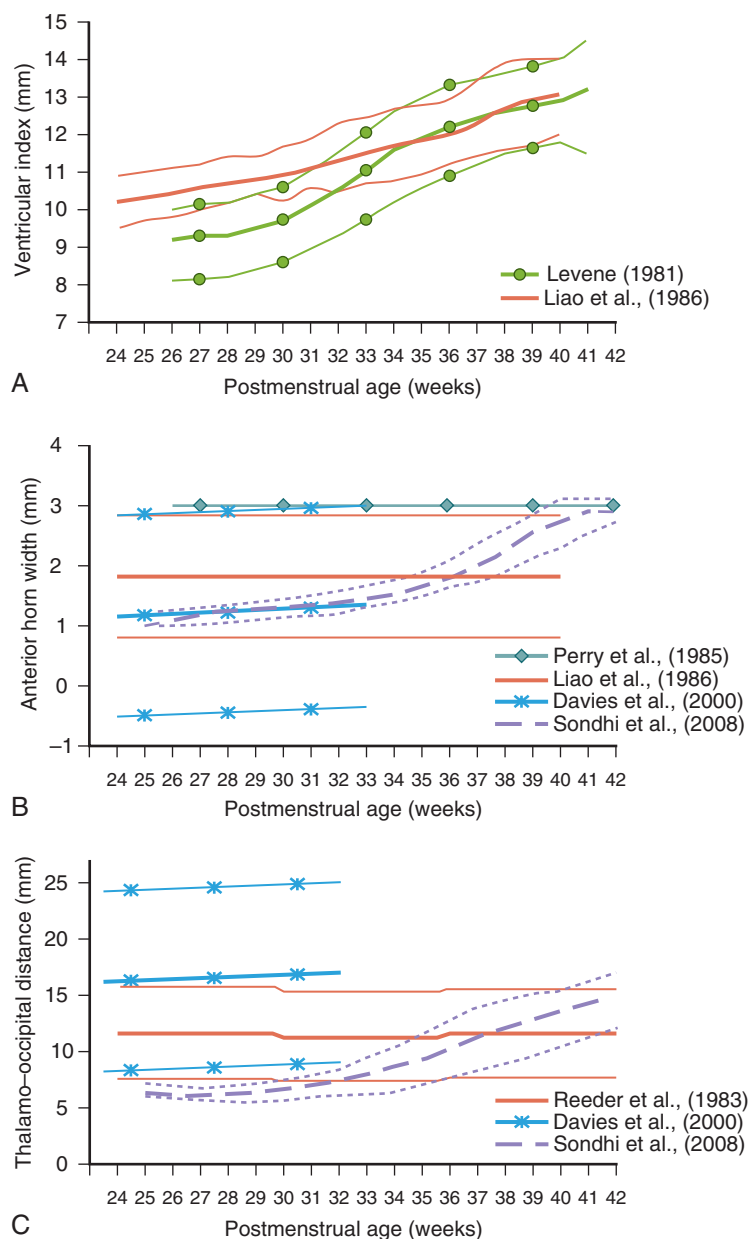

White Matter Injury

Extensive cystic white matter injury (Fig. 63.14), or c-PVL, is now a relatively uncommon problem in very and extremely preterm neonates, with subtle white matter injury now recognized more commonly, particularly on MRI, in this population (Hamrick et al., 2004; Kidokoro et al., 2014). CUS is relatively limited for showing these more subtle white matter lesions (Inder et al., 2003), but nonhemorrhagic injury can sometimes be detected. It has been suggested that any abnormality in the cerebral white matter of echo density at least as echogenic as the choroid plexus and persisting for at least 7 days is significant. Furthermore, the presence of white matter inhomogeneity or a "patchy" appearance on CUS should also alert the clinician to potential white matter abnormalities (Fig. 63.15) (van Wezel-Meijler et al., 2011). These lesions can be hemorrhagic or ischemic in origin, and a combination of diffusion-weighted and susceptibility-weighted MRI can help distinguish between the two (Niwa et al., 2011). They also can be detected by MRI both early and at term equivalent age, tending to be more abundant on the early MRI. Thus early MRI shows the full extent of the white matter lesions, while MRI at term equivalent age identifies the remaining lesions and shows early glial scarring and associated white matter volume loss (Fig. 63.16). Another, more confluent MRI white matter signal abnormality, known as diffuse excessive high signal intensity, has also been described. It is seen on T₂-weighted images at term equivalent age (Counsell et al., 2003) and is a common finding (Dyet et al., 2006). While these white matter signal intensity changes are associated with increased ADC values on diffusion imaging, the qualitative identification of signal changes on T₂-weighted images is rather subjective, and recent studies have failed to identify a relationship between these signal changes and outcome at either 18 or 30 months of age (Kidokoro et al., 2011; Skiold et al., 2012).

As noted above, extensive c-PVL, which is readily visible with both CUS and MRI, has declined over the last decades and now has an incidence of less than 1% in some cohort studies (van Haastert et al., 2011). There is also more localized variant c-PVL. This variant is also relatively uncommon but is more difficult to detect, requiring repeated cranial ultrasound examinations for at least 4–6 weeks for its identification. The cysts are typically located in the frontoparietal white matter adjacent to the lateral border of the lateral ventricles and extend to the occipital white matter in more severe cases. They are usually only visible for a few weeks and may have fully resolved by term equivalent, but their appearance is predictive of subsequent cerebral palsy (CP) (de Vries et al., 2004). Their "resolution" is probably due to coalescence of the cysts with the adjacent lateral ventricle. As a result, their manifestation on MRI at term equivalent may be subtle, consisting of mild to moderate ventricular dilatation and an irregularly contoured ventricular wall. Detection of these transient cystic changes by CUS can be challenging. The American Academy of Neurology recommended in 2002 that all preterm neonates (<30 weeks' gestation) undergo one CUS at 7–14 days for identification of large hemorrhages and a second CUS at 36–40 weeks to identify cystic lesions or ventriculomegaly for prediction of long-term outcome (Ment et al., 2002). However, transient periventricular cystic change may be missed using this protocol. Furthermore, in a study of 1473 extremely low birth weight infants (<1000 g) with only two CUS studies done at mean ages of 6 and 47 days, 29% of those with normal CUS studies had CP or a Bayley Mental Developmental Index less than 70 at 18–22 months of age (Laptook et al., 2005). Thus the finding of two normal CUS studies does

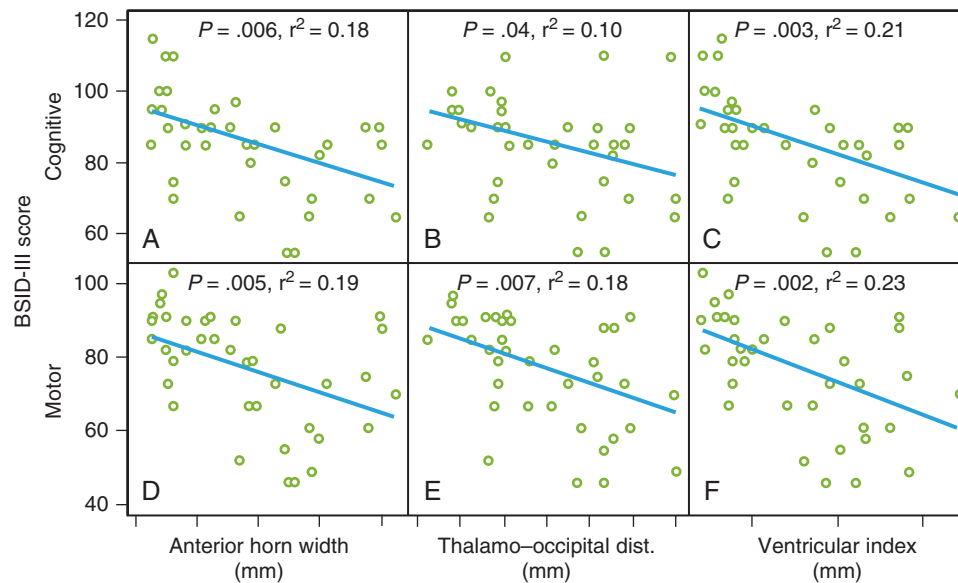

• **Fig. 63.11** Grade IV Intraventricular Hemorrhage With Complicating Periventricular Hemorrhagic Infarction in a Preterm Neonate Born at 24 Weeks' Gestation. (A) Cranial ultrasonography (CUS) on day 2 of life shows a large left-sided intraventricular hemorrhage (IVH) with intraparenchymal echodensity consistent with a periventricular hemorrhagic infarction (PVHI). (B) CUS on day 12 of life shows a significant increase in ventricular size. (C) Coronal and (D) sagittal CUS studies on day 20 of life show significant ventricular dilatation with a thalamo-occipital diameter of 33 mm (measured between the yellow crosses on the thalamus, labeled 1, and the occipital horn of the lateral ventricle) one day before a subgaleal shunt was inserted. (E) Sagittal CUS on day 40 of life showing a left porencephalic cyst resulting from the PVHI. Note that ventricular size is reduced following insertion of the subgaleal shunt. (F) Magnetic resonance imaging at day 84 of life (36 weeks' postmenstrual age) demonstrating asymmetric ventriculomegaly caused by ex vacuo loss of volume in the left hemisphere. There is also left thalamic injury with hemosiderin present. There is an imaging artifact caused by magnetic susceptibility effects over the right hemisphere surface from the subgaleal shunt. Note that the gyral development remains immature for 36 weeks' postmenstrual age.

• **Fig. 63.12** Overview of the reference curves for the (A) ventricular index, (B) anterior horn width, and (C) thalamo-occipital distance according to Davies et al., (2000). Regression lines with 95% confidence intervals are from (Levene, 1981) and (Liao et al., 1986). Also adapted from (Brouwer et al., 2012). AHW, Anterior horn width; TOD, thalamo-occipital distance; VI, ventricular distance. (Data from Brouwer AJ, Brouwer MJ, Groenendaal F, Benders MJ, Whitelaw A, de Vries LS. not have a strong positive predictive value for normal neurodevelopmental outcome. Some centers obtain more frequent CUS studies of very preterm neonates in order to better delineate the nature and progression of intracranial lesions with the hopes of improving prognostic ability (Table 63.3) (Wezel-Meijler and de Vries, 2014). While the relative lack of sensitivity of CUS for injury leading to

neurodevelopmental impairment may be due, to some degree, to missing transient abnormalities, its inability to detect more subtle forms of brain injury, such as diffuse PVL at any time, undoubtedly also contributes. The prevalence of the various types of white matter abnormalities for preterm and term control neonates at term equivalent age is shown in Table 63.4.

• **Fig. 63.13** Bayley Scales of Infant Development Scores for Motor and Cognition at 18–24 Months in 173 Preterm Neonates With Grade III–IV Intraventricular Hemorrhage. *BSID-III*, Bayley Scales of Infant Development. • **Fig. 63.14** Cystic periventricular leukomalacia visible on (A) cranial ultrasound at 28 days of age and (B) magnetic resonance imaging at term equivalent age. Note also the more widespread loss of white matter volume, immature gyral folding, and loss of thalamic volume on the magnetic resonance imaging study.

Cerebellar Hemorrhage

Cerebellar hemorrhage (CBH) is increasingly recognized in the very preterm neonate. This is probably the result of two key factors—the improved survival of extremely preterm neonates (24–28 weeks' gestation) who are at greatest risk for CBH and more routine use of the mastoid window in CUS evaluations (see Fig. 63.1) (Limperopoulos et al., 2005; Steggerda et al., 2009; Ecury-Goossens et al., 2010). The cerebellum undergoes rapid and complex development during the preterm period. From 24–40 weeks' gestation, the cerebellar volume, as assessed with three-dimensional volumetric ultrasound, increases fivefold, and the surface area of the cerebellar

cortex increases more than 30-fold (Volpe, 2009b). Based on CUS, the reported incidence of CBH ranges from 2%–9% depending on the gestational age of the population studied. When MRI is performed as well, the incidence is much higher, ranging from 15%–20% (Limperopoulos et al., 2005; Steggerda et al., 2013). This may be because CUS is only sensitive to hemorrhages that are more than 4–5 mm in size. Smaller, punctate CBHs are far more common but can only be diagnosed with MRI, particularly susceptibility-weighted images (Parodi et al., 2015; Plaisier et al., 2015). Of note, larger CBHs tend to be associated with supratentorial lesions such as IVH and evolve to atrophy of the affected cerebellar hemisphere on MRI at term equivalent age.

• **Fig. 63.15** White matter echo density in a 28-week preterm neonate comparing cranial ultrasound on day 5 of life (left) with linear hemorrhagic lesions in the periventricular white matter (red arrow) and thalamus (white arrow) on term equivalent magnetic resonance imaging.

• **Fig. 63.16** White matter lesions (arrows) for (A) focal small punctate lesions, (B) multiple focal punctate lesions, and (C) linear hyperintensity in the periventricular white matter.

Predicting Outcome With Imaging at Term Equivalent Age

Clinicians and researchers continue to possess limited ability to definitively predict and meaningfully improve neurodevelopmental outcomes. While both CUS and MRI have value in this regard, neither is perfect (Table 63.5) (de Vries et al., 2013a). As noted above, CUS is strongly predictive of subsequent cerebral palsy, in the right hands (de Vries et al., 2004), but normal CUS studies are not good predictors of normal neurodevelopmental outcome. MRI is significantly more sensitive to subtle injuries to white matter and cerebellum. Below, we briefly outline the literature on MRI at term equivalent age and outcome for preterm neonates.

Structural Magnetic Resonance Imaging

There is an increasing amount of literature available on the association of white matter abnormalities with structural MRI and neurodevelopmental outcome. White matter abnormalities have been associated not only with motor difficulties (Spittle et al., 2011) but also with impairments in executive functioning (Edgin et al., 2008; Woodward et al., 2011), verbal and visuospatial working memory (Clark and Woodward, 2010), language skills (Foster-Cohen et al., 2010; Reidy et al., 2013), and learning and attention (Murray et al., 2014; Omizzolo et al., 2014). Cortical gray matter abnormalities can also be detected with structural MRI, but gray matter tissue signal abnormalities in preterm neonates are less

common than white matter signal abnormalities, and gray matter injury is more typically manifest as alterations of cortical folding and enlarged extracerebral spaces. In a study of 167 very preterm neonates, gray matter abnormalities were found in half of the neonates and consisted of abnormal/immature cortical folding patterns and/or enlarged subarachnoid space (Woodward et al., 2006). These abnormalities were associated with an increased risk of severe cognitive delay, psychomotor delay, and CP at age 2 but to a lesser extent than white matter abnormalities (Woodward et al., 2006). In contrast, a study of 76 preterm neonates in which

a similar scoring system for gray matter abnormality was used found no association between gray matter abnormality and outcome at age 9 years (Iwata et al., 2012). It is worth noting that alterations of cortical folding and enlarged extracerebral spaces involve both gray and white matter. Cortical folding probably represents an interaction between cortical gray matter and underlying white matter, whereas enlarged extracerebral spaces may reflect an overall reduction in cerebral volume involving multiple brain tissue types.

The literature on cerebellar abnormalities detected by structural MRI and outcome in preterm neonates is relatively sparse, but cerebellar injury is associated with adverse neurodevelopmental outcome. Neonates with isolated cerebellar lesions have a range of neurodevelopmental deficits, including severe motor disabilities, abnormalities of expressive and receptive language, and cognitive deficits (Limperopoulos et al., 2007). They additionally experience a higher incidence of autism and behavioral dysfunction (Brossard-Racine et al., 2015). Isolated cerebellar injury has also been associated with impairment of regional volumetric growth in the contralateral cerebrum, with corresponding deficits of language, motor, and social-behavioral function (Bolduc et al., 2011; Limperopoulos et al., 2014).

While structural MRI is often helpful for predicting neurodevelopmental outcome of preterm neonates, a relatively high proportion of neonates without any evidence of brain injury (IVH, PVL, or CBH) have abnormal outcomes. For example, in one study the mean mental developmental index of preterm neonates with normal structural MRI was 87, with a 6% incidence of cerebral palsy (Kidokoro et al., 2014). In a metaanalysis of the prognostic accuracy of abnormalities on term MRI for predicting long-term outcome in preterm neonates (Van't Hooft et al., 2015), the sensitivity and specificity for predicting CP were 77% and 79%, respectively. The corresponding values for predicting cognitive impairment were 66% and 61%. It is important to note that the analysis was done

^aMajor abnormalities: IVH grades III–IV, hemorrhage of the brain parenchyma, white matter cysts, abnormal T1 or T2 signals in cortex, basal ganglia, thalamus, cerebellum or internal capsule, abnormality of the corpus callosum, an extracerebral space width of 6 mm or more, and ventriculitis.

^bSevere CUS: multicystic PVL and/or focal echodensities within the white matter; severely abnormal MRI: extensive SI changes with hemorrhagic or (pre)cystic lesions in the periventricular white matter, with periventricular and/or subcortical extension.

cPVL, Cystic periventricular leukomalacia; CUS, cranial ultrasonography; FI, focal infarction; IVH, intraventricular hemorrhage; MRI, magnetic resonance imaging; NPV, negative predictive value; PPV, positive predictive value; PVL, periventricular leukomalacia; SI, signal intensity; TEA, term equivalent age; WMI, white matter injury.

on a small number of studies, with only two or three studies included in each category of outcome, underscoring the serious need for more research in this area. Nevertheless, the relative lack of sensitivity of structural MRI for identifying brain injury in the preterm neonate has led to a search for more sensitive approaches, including volumetric studies, diffusion imaging analysis, and functional connectivity MRI, in hopes of finding more sensitive and accurate predictors of outcome.

As above, the finding of enlarged extracerebral spaces on term equivalent MRI may reflect a small brain caused by volume loss and/or poor growth as a consequence of injury and undernutrition during the period from preterm birth to term age. For research studies, brain volume can be quantified with more specificity: i.e., after segmenting brain into tissue classes such as cortical gray matter, white matter, deep nuclear gray matter, brainstem, and cerebellum. Widespread alterations in cerebral volumes have been described for preterm neonates imaged at term age (Huppi et al., 1998b), and a number of studies have related volume changes with neurodevelopmental outcome. At short-term follow-up (< 2 years), neurodevelopmental disability was associated with reduced cortical and deep nuclear gray matter volumes, increased CSF volume (Inder et al., 2005; Young et al., 2015), reduced white matter volume (Peterson et al., 2003), reduced hippocampal volume (Beauchamp et al., 2008; Thompson et al., 2008), reduced total cerebral tissue volume (Woodward et al., 2005), and reduced cerebellar volume (Van Kooij et al., 2012a). At 5 years, a relationship was found between reduced cerebellar volume and poorer executive function and motor skills (Lind et al., 2010). Finally, smaller infant

hippocampal volumes were associated with lower verbal memory scores at 7 years of age (Thompson et al., 2013). Volumetric analysis of infant brain MR images requires specialized computer software and, often, user intervention to ensure that segmentations are done correctly, which hampers the use of these measures in routine clinical practice. Simpler, one-dimensional measures from structural MR images are highly correlated with volumes and could potentially be useful in a clinical setting (Nguyen The Tich et al., 2009). For example, biparietal diameter, which correlates with overall brain volume, was predictive of cognitive and motor outcomes in 2-year-old subjects after adjustment for perinatal variables and social risk (Tich et al., 2011).

Diffusion Magnetic Resonance Imaging

Diffusion MRI is unique in that it provides aspects of both structural and functional information. The rapid reduction in brain water ADC associated with acute brain injury reflects an alteration in brain “function” in the sense that this reduction takes place within minutes of injury, a much shorter time frame than that of the structural changes that are subsequently detectable by histology. For the discussion here, we focus more on the microstructural information available through diffusion imaging. This information is most commonly applied to white matter and is encoded as diffusion anisotropy. Traditionally, higher anisotropy is taken to reflect “healthier” or more “ordered” white matter.

During early brain development, overall water diffusion coefficients decrease steadily, most likely as a reflection of the reduction

in brain water content that accompanies maturation. Diffusion anisotropy values in white matter, on the other hand, increase during development in association with myelination (Huppi et al., 1998a; Neil et al., 1998). As noted above, the most common white matter injury in preterm neonates is characterized by diffuse white matter changes. This diffuse injury is defined histologically (Volpe, 2009a), but diffusion imaging provides supporting evidence for its presence in the form of globally reduced white matter diffusion anisotropy values in preterm neonates (Huppi et al., 2001).

Abnormalities of diffusion have been correlated with neurodevelopmental outcome as well. For infants evaluated at less than 2 years old, high diffusion coefficient values for white matter (Kaukola et al., 2010) and cerebellum (Brouwer et al., 2014) were associated with worse motor outcomes. Low white matter anisotropy values, particularly in the posterior limb of the internal capsule and corpus callosum, were also associated with poor motor outcomes (Arzoumanian et al., 2003; Drobyshevsky et al., 2007; Rose et al., 2009; van Kooij et al., 2012b; Chau et al., 2013; De Bruine et al., 2013). In longitudinal studies of preterm children at ages 4 through 7 years, high ADC values in the right orbitofrontal area have been associated with social-emotional problems (Rogers et al., 2012), and high ADC values in regions of the occipital pole and cerebellum were associated with impairment of motor and executive function (Thompson et al., 2014). In addition, low anisotropy values in the posterior limb of the internal capsule were associated with poor motor outcome at age 4 years (Rose et al., 2007).

In the studies outlined above, low white matter anisotropy was associated with impaired outcome, but this relationship is not universal. In a study of preterm children evaluated at age 2 years, lower anisotropy in the right inferior temporal lobe, but higher anisotropy in the left inferior temporal lobe, was associated with lower motor scores. In another study, lower anisotropy in the left cingulum bundle was associated with better social-emotional competence (Rogers et al., 2016). These results are consistent with diffusion studies on older subjects with autism and other developmental impairments (Cheon et al., 2011). The microstructural alterations underlying these opposing results are not fully understood. It has been hypothesized that reduced axonal branching or fewer fiber tracts crossing the tract of interest may lead to higher anisotropy in injured white matter areas.

Term Neonates

Neonatal Encephalopathy

Among the clinical indications for neuroimaging studies from term neonates, the presence of neonatal encephalopathy is the most common. Neonatal encephalopathy has been defined as “a clinically defined syndrome of disturbed neurologic function in the earliest days of life in the term infant, manifested by difficulty with initiating and maintaining respiration, depression of tone and reflexes, subnormal level of consciousness, and often by seizures” (Nelson and Leviton, 1991). It affects 2–6 per 1000 live births, has a 15%–20% mortality rate, and 25% of survivors are left with severe disability. It is important to bear in mind that not all neonatal encephalopathy is caused by intrapartum ischemia (Kurinczuk et al., 2010). It has been estimated that on the order of 40% is due to other causes such as infection, stroke, metabolic disorder, and genetic disorders (Shah et al., 2006). The common patterns of brain injury in the encephalopathic term neonate include diffuse global injury, deep nuclear gray matter injury, brainstem injury, watershed injury, periventricular white matter injury, and focal

infarction. Of these, deep nuclear gray matter injury (25%–75% of cases) and watershed injury (15%–45% of cases) are most common (Barkovich et al., 1998; Task Force on Neonatal Encephalopathy, 2014). Deep nuclear gray matter injury involves the deep gray nuclei and perirolandic cortex, extending further into the cortex when severe. The watershed pattern involves injury at the watershed areas between the anterior and middle cerebral arteries anteriorly and the middle and posterior cerebral arteries posteriorly. Watershed injury may be unilateral or bilateral and affect the anterior watershed, the posterior watershed, or both. It primarily involves white matter but can extend into the cortical gray matter in severe cases. An example of each category of injury is shown in Fig. 63.17. From a clinical standpoint, the two forms of injury tend to be associated with different clinical scenarios. The watershed pattern of injury often follows normal labor with minimal resuscitation, relatively good Apgar scores, and an umbilical cord pH of greater than 7.00. During the postnatal period, the watershed pattern of injury is typically associated with proximal limb weakness, truncal hypotonia, and a relatively high incidence of seizures. Later in life, this injury pattern is associated with predominantly cognitive impairments with fewer functional motor deficits (Miller et al., 2005). The deep nuclear gray matter pattern of injury, on the other hand, often follows a sentinel event (e.g., cord prolapse, placental abruption, or uterine rupture) with low Apgar scores and an umbilical cord pH of less than 7.00. These neonates are more profoundly encephalopathic and may have evidence of multiorgan injury involving the heart, kidneys, and liver. During the postnatal period they are often hypotonic and feed poorly. Subsequent neurologic impairment tends to be more severe in these patients and depends on the extent of injury, as has been outlined by Martinez-Biarge et al. (2010). Furthermore, signal abnormality in the posterior limb of the internal capsule on MR imaging has a strong association with subsequent motor deficit in these neonates (Martinez-Biarge et al., 2011). It is important to bear in mind that while the patterns described here are usually associated with hypoxic-ischemic injury, there are mimics of these patterns associated with other causes such as meningitis (Hernandez et al., 2011) and metabolic disorders (Johnston and Hoon, 2000). Thus the presence of either of these patterns on MRI may be consistent with a hypoxic-ischemic insult but does not prove that one occurred. Thus the clinician should be wary.

In addition to the findings derived from conventional and diffusion imaging, spectroscopy can also provide information regarding prognosis. A rise in lactate and fall in NAA are the most significant changes observed, with lactate being detected within 24 hours following injury and NAA beginning to decrease after 48 hours (Barkovich et al., 1999). Elevated lactate levels are seen for months after injury and thus do not always indicate acute injury, although the persistence of lactate signal signifies a worse prognosis (Miller et al., 2002). In a metaanalysis of 32 studies grouping 806 newborns with neonatal encephalopathy, the lactate/NAA ratio in the deep gray matter had strong prognostic accuracy for disability, with a pooled sensitivity of 82% and a specificity of 92% (Thayyil et al., 2010). Although this measure was useful for predicting death or profound disability, more detailed anatomic imaging may assist in refining prognostic information. A study of term neonates who underwent conventional diffusion MRI and spectroscopy measurements in the basal ganglia at a median of day 4 of life showed that the addition of quantitative measures ADC, lactate/NAA, or both improved the predictive power for conventional imaging for adverse neurodevelopmental outcome (for lactate/NAA, area under the curve [AUC] = .85 and $P = .006$;

• **Fig. 63.17** Common Patterns of Cerebral Injury. These are diffusion images obtained 2–4 days after injury in which areas of injury appear bright (arrow). | Parenchymal | 37 (5%) | 57 (12%) | 105 (10%) |
| Deep nuclear gray matter injury | 70 (10%) | 50 (10%) | 309 (29%) |
| White matter injury | 16 (2%) | 15 (3%) | 271 (25%) |

IVH, Intraventricular hemorrhage; SD, standard deviation; SE, subependymal hemorrhage.

for ADC values from the basal ganglia, AUC = .93 and $P < .001$) (Alderliesten et al., 2011).

Different imaging modalities—CUS, CT, and MRI—provide different information for patients with neonatal encephalopathy. Table 63.6 shows data from the Vermont Oxford Neonatal Encephalopathy Registry on the clinical application of these modalities (Task Force on Neonatal Encephalopathy, 2014). Note that all three modalities remain in fairly wide use. Note also that the mean time to obtaining the imaging study varies by modality, with CUS and CT being performed at a mean age of 3 days as compared with 7 days for MRI. This probably reflects the more demanding logistics of moving a neonate to the MRI suite for study. However, MRI outperforms both CUS and CT for detection of abnormalities, detecting injury in 67% of cases as opposed to

32% and 57%, respectively. Importantly, the additional injuries detected by MRI are clinically relevant. While CUS and CT show sensitivity mainly for intraventricular and extraaxial hemorrhage, MRI is much more sensitive to injury to deep nuclear gray matter and white matter (e.g., watershed injury). For neonates with neonatal encephalopathy, the American College of Obstetrics and Gynecology (with the endorsement of the American Academy of Pediatrics) suggests that information regarding the likely timing of injury is best obtained with early imaging (during the first 24–96 hours of life) with follow-up imaging to define the full nature of the abnormalities, optimally at 10 days of life (but with an acceptable window between 7 and 21 days of life) (American College of Obstetrics and Gynecology, 2014). This recommendation is supported by the finding that the extent of injury may change in up

to 20% of neonates on images obtained between days 3–4 and those obtained later (>7 days), particularly in neonates with hypoglycemia and moderate–severe lesions in the deep nuclear gray matter (Chakkarapani et al., 2016). However, from a practical standpoint, often only a single MRI study can be obtained. In that circumstance, we recommend that the single study be obtained later than 1 week after the initial insult and as late as feasible. Finally, it may be useful to obtain an MRI study earlier than days 3–4 in some instances, for example, to confirm the absence of injury in neonates for whom early rewarming is being considered (often in association with a normal examination and electroencephalography). Another instance is to confirm the severity of injury in profoundly encephalopathic neonates for whom redirection of care is under consideration. In this case, diffusion MRI will very likely show the injury from its onset, and MR spectroscopy (lactate/NAA ratio) will be informative.

Sinovenous Thrombosis

Neuroimaging is necessary for detecting sinovenous thrombosis as well as following patient response to therapy. Sinovenous thrombosis is less common than neonatal encephalopathy and has an incidence of 2–12 per 100,000. Infants usually present with seizures and/or encephalopathy. Risk factors for sinovenous thrombosis include hypoxic–ischemic encephalopathy, complicated delivery, complicated pregnancy, dehydration, prematurity, congenital heart disease, sepsis, and prothrombotic abnormalities (Moharir et al., 2011). From an imaging standpoint, sinovenous thrombosis is often initially detected by CUS or MRI as IVH with or without associated thalamic hemorrhage (Fig. 63.18). The presence of a clot in a sinus may sometimes be visible as an area of high signal intensity (bright) on T₁-weighted imaging. When these findings are present, MR venography is very helpful for delineating the thrombosis, and involvement of multiple sinuses and veins is relatively common. Identifying the extent of thrombosis is important because it is a treatable condition, and it is common to use anticoagulant therapy (cautiously, in the presence of significant hemorrhagic injury). MR venography provides a means of evaluating the response to anticoagulant therapy, and follow-up imaging is typically obtained some weeks following the initiation of therapy.

Stroke

Perinatal stroke has been defined as focal ischemic brain injury secondary to vascular occlusion (Kirton and deVeber, 2009). It has an incidence of approximately 1 per 5000 live births, making it much more common than sinovenous thrombosis. As described in detail above, the appearance of stroke evolves over time. It is initially most readily detected by diffusion MR and is subsequently visible on T₁-weighted and T₂-weighted images (Fig. 63.19). In the case of nonhemorrhagic stroke, MRI is considerably more sensitive than CUS or CT, making MRI the preferred imaging modality. Because focal neurologic signs are relatively rare in newborns with stroke, it is not uncommon for perinatal strokes to go undiagnosed until later in the first year or so of life when neurologic deficits (typically hemiparesis) become obvious. In a study of 248 neonates with arterial ischemic stroke, part of the International Pediatric Stroke Study (Kirton et al., 2011), 72% presented with seizures and 63% with nonfocal neurologic signs. Once stroke is detected, consideration should be given to MR angiography to more fully define the anatomy of the injury. In the International Pediatric Stroke Study (Kirton et al., 2011),

infarcts preferentially involved the anterior circulation and the left hemisphere and were multifocal in 30% of neonates. The causes of neonatal stroke are often obscure, with cardiac and prothrombotic abnormalities identified in less than 20% of the newborns. Research on neurologic outcome following stroke is relatively sparse (Lehman and Rivkin, 2014), although clinical experience suggests that neonates have a much greater capacity for recovery than adults with similar injuries. For example, in neonates with middle cerebral artery occlusion, hemiparesis is only present in 26% of children by age 2 years, although this number increases to 50%–70% when there is corticospinal tract involvement on MRI (Husson et al., 2010).

Vein of Galen Malformation

Vein of Galen malformation is the most common arteriovenous malformation of the newborn, and the majority are identified during the neonatal period. The malformation is associated with dilatation of the vein of Galen and straight sinus extending to the torcula (Fig. 63.20). Newborns often present with hydrocephalus caused by compression of the cerebral aqueduct or high-output cardiac failure. Seizures are also not uncommon. Prognosis depends upon the size of the malformation, age at diagnosis, and successful neurosurgical outcome.

Infection

The imaging appearance of infection is remarkably diverse, varying not only with the infectious agent but also having different appearances with the same infectious agent (Table 63.7). For example, the brain injury associated with bacterial meningitis includes watershed injury, arterial occlusion with stroke, capillary thrombosis with smaller areas of injury, and sinovenous thrombosis, all of which have a characteristic appearance on MRI. As noted above, bacterial meningitis may very closely mimic hypoxic–ischemic injury (Hernandez et al., 2011). The characteristic abnormalities associated with congenital cytomegalovirus infection are shown in Fig. 63.21. The marked predilection for parechovirus (which is postnatally acquired) for white matter is evident in Fig. 63.22.

Other Intracranial Hemorrhages

Aside from the IVHs described in detail above for preterm neonates, the other major, clinically important types of neonatal intracranial hemorrhage are: (1) epidural hemorrhage, (2) subdural hemorrhage, including posterior fossa subdural hemorrhages, (3) primary subarachnoid hemorrhage, and (4) other forms of intraparenchymal hemorrhages (other than cerebellar). The approximate incidence, anatomic site of blood, relative frequency in preterm versus term born neonates, and the usual clinical gravity of these hemorrhages, including CBH and IVH, are noted in Table 63.8.

The incidence of intracranial hemorrhage has been challenging to define, as most studies have focused on symptomatic newborns, and some hemorrhages are asymptomatic. In one small study of symptomatic newborns, the estimated incidence was 4.9 per 10,000 live births (Hanigan et al., 1995). The largest epidemiologic data relate to the Californian Perinatal Database, which includes maternal and neonatal hospital discharge records on 600,000 infants (2500–4000 g) born to nulliparous women. In this study, the incidence of symptomatic intracranial hemorrhage associated with spontaneous delivery was 1 per 1900 births, vacuum extraction delivery was 1 per 860 births, and forceps delivery was 1 per 664

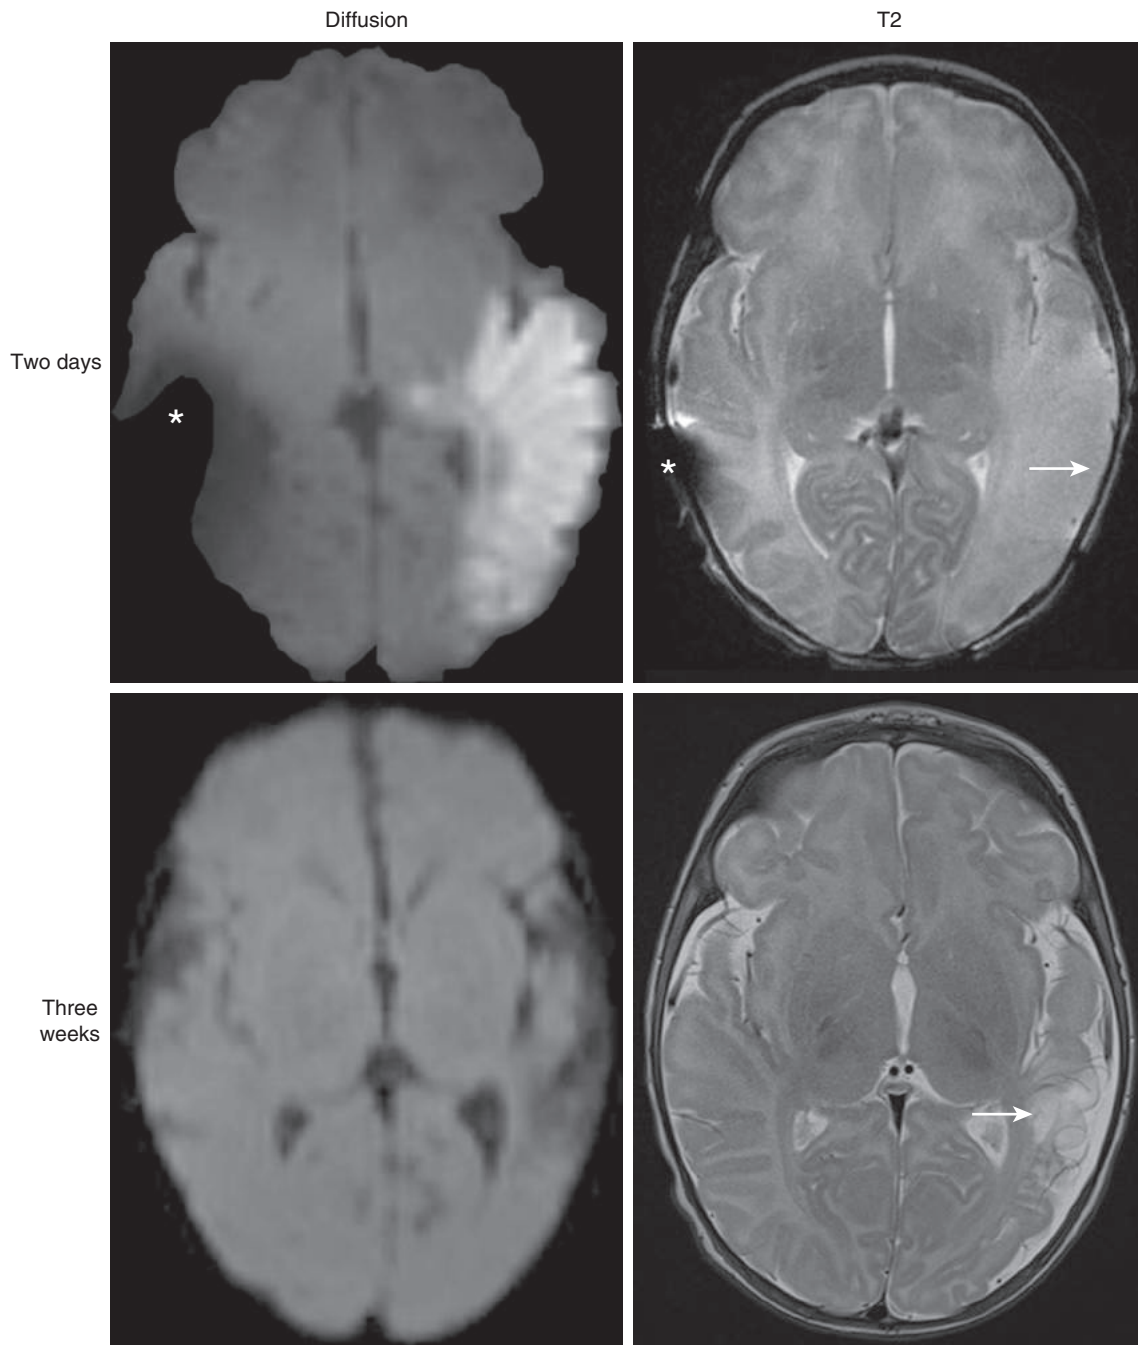

• **Fig. 63.18** Images From a Term Newborn With Sinus Thrombosis. (A) A coronal cranial ultrasonography (CUS) image with a bright-appearing thalamic hemorrhage (arrow). (B) A parasagittal view of the left lateral ventricle. Note the thalamic hemorrhage (arrow) and blood in the occipital horn of the ventricle (arrowhead). (C) The coronal T₁-weighted magnetic resonance (MR) image corresponding to the CUS image in A. The thalamic hemorrhage appears bright (arrow). (D) An axial T₂-weighted MR image in which hemorrhage appears dark. Note the thalamic hemorrhage (arrow) and blood in the lateral ventricles (arrowheads).

births (Towner et al., 1999). In contrast, more recent studies utilizing MRI in asymptomatic newborns in the first month of life have revealed a much higher frequency of intracranial hemorrhage. A large prospective study found an 8% prevalence of subdural hemorrhage in this population (Whitby et al., 2004; Rooks et al., 2008). A second study of 88 asymptomatic neonates born via vaginal delivery who underwent MRI between the ages of 1 and 5 weeks demonstrated 17 term neonates with intracranial hemorrhage for a study prevalence of 26% (Looney et al., 2007). Such findings suggest that asymptomatic intracranial hemorrhage in term newborns is more frequent than previously thought.

With these limitations regarding the incidence of intracranial hemorrhage in mind, Table 63.8 provides a summary of the

location, incidence, and usual clinical outcomes of the main types of hemorrhage. Note that subdural hemorrhage is more frequent in the term neonate than in the preterm neonate and is frequently asymptomatic but can be clinically serious if large. Primary subarachnoid hemorrhage is more frequent in the preterm neonate than in the term neonate and is fairly common but is almost always clinically benign. Cerebellar hemorrhage is more frequent in the preterm neonate than in the term neonate and can have developmental consequences as outlined above. As also outlined above, IVH, almost exclusively a lesion of the preterm neonate, affects developmental outcome. IVH recently has been more commonly recognized in the term-born infant, particularly in relation to sinovenous thrombosis and/or hypoxic-ischemic

• **Fig. 63.19** Images from a term newborn who presented with episodes of rhythmic jerking of the right upper and lower extremities with rightward eye deviation at approximately 24 hours of age. Note the area of stroke on the diffusion image at age 2 days (top left), which appears bright (representing a low apparent diffusion coefficient value). Note also that the injury is visible on the T_2 -weighted image (top right), in this case as loss of the cortical ribbon (*arrow*). The *asterisk* on each image denotes an area of magnetic susceptibility artifact. The lower row images were obtained at age 3 weeks. Note that the injury is no longer detectable on diffusion imaging (bottom left) but is now an area of encephalomalacia on the T_2 -weighted image (bottom right; *arrow*).

cerebral injury. Other forms of intraparenchymal hemorrhage, more frequent in the term neonate than in the preterm neonate, are uncommon.

The three primary brain imaging modalities—CUS, CT, and MRI—have different sensitivities for detecting hemorrhage. As noted above, CUS is the method of choice for evaluating IVH

in preterm neonates because of its suitability for serial imaging of critically ill neonates. However, CUS is not the modality of choice for all forms of hemorrhage. In a study analyzing 4171 term-born infants, imaging was performed for 2006 patients with CUS, 933 patients with CT, and 2690 patients with MRI. Although cranial ultrasound identified IVH well, it lacked the

• **Fig. 63.20** Images From a Term Newborn With Vein of Galen Malformation. (A, B) Note the large flow void on the T₂-weighted images. (C) The corresponding angiogram. (Images courtesy of Dr. Bob McKinstry.)

sensitivity of MRI and CT for identifying other types of hemorrhage and intracranial injury and was particularly limited for the detection of extraaxial hemorrhage (subdural, subarachnoid, and extradural) (Pfister et al., 2012; Barnette et al., 2014). CT was recommended in the 2002 American Academy of Neurology practice parameters for neonates with birth trauma and a low hematocrit or coagulopathy (Ment et al., 2002) on the basis of data from two small studies reporting on CT diagnoses of intracranial hemorrhages leading to interventions (Odita and Hebi, 1996; Perrin et al., 1997). Although the authors were unable to determine the impact of the imaging findings on the neonates who needed surgical intervention, only 9 of 933 neonates with CT examinations underwent any central nervous system surgery. Given the risks of radiation exposure associated with CT imaging, we suggest using MRI, when available, to detect extraaxial hemorrhage. The use of MRI has the added benefit of better sensitivity for detecting parenchymal injury than CT. Development of more rapid MRI sequences to allow for shorter studies to detect cerebral hemorrhage should enhance physician comfort with this as a first-line technique.

Subdural Hemorrhage

MRI is more effective than CT in the delineation of posterior fossa subdural hemorrhage (Barkovich, 2005). Detection of subdural hematoma by ultrasound scanning, although reported, generally is difficult. Moreover, even when these hematomas are detected, the extent and distribution of supratentorial lesions are usually demonstrated far better by MRI or CT and infratentorial lesions are detected better by MRI. In addition, the vast majority of subdural hematomas are infratentorial, where ultrasound has even greater challenges in accurate diagnosis (Fig. 63.23).

Subarachnoid Hemorrhage

The diagnosis of primary subarachnoid hemorrhage is usually made by MRI or CT and, on rare occasions, by ultrasound (Barnette et al., 2014). On CT, distinction between the normal, slightly increased attenuation in the regions of the falx and major venous sinuses and the increased attenuation caused by subarachnoid hemorrhage may be difficult. Sometimes, the possibility of primary

**TABLE
63.7****Magnetic Resonance Imaging Findings for Neonatal Infections**

| Infection | Imaging Findings | Infection | Imaging Findings |
|------------------------------|--|---------------------------------------|--|
| Bacterial meningitis | Basal ganglia injury Watershed injury Sinovenous thrombosis Infarct (may be multifocal) Abscess Extraaxial empyema Ventriculomegaly | Varicella (congenital) | Diffuse cerebral necrosis Cerebellar hypoplasia Cortical malformations, including pachygyria |
| Cytomegalovirus (congenital) | Calcifications (periventricular and cortical) Cortical malformations (lissencephaly, polymicrogyria, heterotopias) Ventriculomegaly Cerebellar hypoplasia Periventricular leukomalacia Porencephaly | Herpes simplex (congenital) | Microcephaly with severe volume loss |
| Toxoplasmosis (congenital) | Diffuse cerebral necrosis Porencephaly Hydranencephaly Diffuse cerebral calcifications Periventricular necrosis Hydrocephalus | Herpes simplex (peripartum/postnatal) | Early Multifocal injury Signal abnormality may be limited to the temporal lobes, cerebellum, or brainstem (may be hemorrhagic) Basal ganglia injury Watershed injury Late Multicystic encephalomalacia White and gray matter volume loss Calcification |
| Rubella (congenital) | Periventricular and basal ganglia calcification Ventriculomegaly Multifocal white matter lesions Leukoencephalopathy Subcortical cysts Cortical malformations are uncommon. | Zika (congenital) | Cortical malformations (lissencephaly, heterotopias, polymicrogyria) Parenchymal calcifications Ventriculomegaly Dysgenesis of the corpus callosum Cerebellar hypoplasia Brainstem hypoplasia |
| | | Parechovirus (neonatal) | Diffuse white matter injury with cortical sparing |

**TABLE
63.8****Intracranial Hemorrhage**

| Hemorrhage | Incidence % | Site of Blood | Full Term or Preterm | Usual Clinical Outcome |
|-----------------------|------------------|---|----------------------|------------------------|
| Extradural (Epidural) | Very rare | Between skull and outside of dura | FT > PT | Variable |
| Subdural | 5–25 | Between dura and arachnoid | FT > PT | Benign |
| Subarachnoid | 1–2 FT 10 PT | Between arachnoid and pia | PT > FT | Benign |
| Cerebellar | 0.1 FT 5 PT | Cerebellar hemispheres and/or vermis | PT > FT | Serious |
| Intraventricular | 0.2 FT 15 PT | Within ventricles or including periventricular hemorrhagic infarction | PT > FT | Serious |
| Parenchymal | 0.1 FT 2–4 PT | Cerebral parenchyma | FT > PT | Variable |

FT, Full term; PT, preterm.

subarachnoid hemorrhage is raised initially by the findings of an elevated number of red blood cells and an elevated protein content in the CSF, usually obtained for another purpose (e.g., to rule out meningitis). Exclusion of the relatively common (e.g., extension from subdural, cerebellar, or IVH) and uncommon (e.g., tumor, vascular lesions) causes of blood in the subarachnoid space is best done by MRI.

Ultrasonography is insensitive in detecting subarachnoid hemorrhage because of the normal increase in echogenicity around the periphery of the brain (Shackelford and Volpe, 1985). A large subarachnoid hemorrhage occasionally distends the Sylvian fissure and thus becomes detectable, but care must be taken not to confuse a Sylvian fissure distended with blood from the wide fissure seen consistently in preterm neonates and resulting from the normal

• **Fig. 63.21** A 16-day-old neonate born after 31 weeks' gestation with congenital cytomegalovirus infection identified in utero. (A) An axial T₁-weighted magnetic resonance imaging (MRI) scan shows an increased signal in the periventricular regions (*short arrows*), consistent with calcification, and diffuse polymicrogyria (*long arrow*). (B) Note the striking cerebellar hypoplasia (*arrows*). (C) At 6 months of age, the axial T₂-weighted MRI scan shows diffuse frontal polymicrogyria (*long arrows*), abnormal high signal intensity in cerebral white matter (*short black arrows*), and marked paucity of parieto-occipital cerebral white matter (*double white arrows*). (Courtesy of Dr. Omar Khwaja.)

separation of the frontal operculum and superior temporal region until late in gestation ([Chamnanvanakij and Perlman, 1999](#)).

Methods Not Yet in Clinical Use

Quantitative Interpretation of Magnetic Resonance Imaging Studies

MRI studies are almost universally subjected to qualitative interpretation in the clinical setting. However, a number of quantitative

scoring systems have been devised (see [Table 63.4](#)), though there is no universally accepted, or gold standard, scoring system. Most scoring systems rely upon features of conventional T₁-weighted and T₂-weighted images, with a tendency for some scoring systems to focus mainly on loss of brain volume, while others focus primarily on signal abnormality. Since brain injury during the neonatal period may lead to both poor brain growth (small volume) and injury to remaining tissue (signal abnormality on MRI studies), it is useful to take both into account in a scoring system. To complicate matters further, some scoring systems focus on relatively confined

• **Fig. 63.22** Parechovirus Infection in a Neonate. T₂-weighted (A) and diffusion (B) magnetic resonance images obtained 6 days after the onset of human parechovirus infection in a neonate. (C) A T₁-weighted image obtained at 3 months. Note the multiple punctate white matter lesions (A, arrows) and diffusion abnormality (B, areas of low apparent diffusion coefficient appear bright) in the periventricular white matter and involving the optic radiation and the internal capsule. Note also the areas of high signal intensity in the periventricular white matter present at 3 months of age, suggesting gliosis (C). (Adapted from Verboon-Macielek MA, Groenendaal F, Hahn CD, et al. Human parechovirus causes encephalitis with white matter injury in neonates. *Ann Neurol*. 2008;64:266–273.)

areas of the brain, such as white matter, without evaluation of cortical gray matter, deep nuclear gray matter, and/or the posterior fossa. The broadest scoring system would take both loss of volume and signal abnormality into account for the entire brain and cerebellum (Kidokoro et al., 2013).

Cortical Cartography

In addition to the scoring systems noted above, cortical cartography provides a means by which to quantify MRI studies. Cortical

cartography involves analysis of the cortical surface. With this approach, a surface is generated from conventional images and a number of summary parameters are measured to capture features of the cerebral topography. One of the more common of these is cortical surface area, which increases dramatically during the immediate postnatal period in preterm neonates. A second parameter is the gyrification index, a ratio of surface areas: the numerator is the cortical surface area, and the denominator is the cerebral hull area, which can be imagined as the surface area of cling wrap if it were wrapped around the brain (Van Essen, 2005). For a completely

smooth, or lissencephalic, brain, the gyrification index would be 1. As the number and depth of cortical folds increase the gyrification index increases. As would be expected, the gyrification index increases during normal brain development (Shimony et al., 2016). As for cortical surface area, the gyrification index is affected by preterm birth and is lower for preterm neonates at term equivalent age compared with control neonates in a region-specific fashion (Engelhardt et al., 2015). Gyrification index values have also been related to neurodevelopmental outcome (Dubois et al., 2008a). A third index derived from cortical cartography is sulcal depth, which is the distance between the cerebral hull and the bottom of each sulcus (Van Essen, 2005). As with the other parameters, sulcal depth increases with brain development (Dubois et al., 2008b; Zubiaurre-Elorza et al., 2009; Shimony et al., 2016), and abnormalities of sulcal depth have been described for preterm neonates (Engelhardt et al., 2015).

• **Fig. 63.23** Tentorial Subdural Hemorrhage With Blood Layering Along Both Leaves of the Tentorium and Posterior Falx. (Adapted from Castillo M, Fordham LA. MR of neurologically symptomatic newborns after vacuum extraction delivery. *AJNR Am J Neuroradiol.* 1995;16:816–818.)

Functional Magnetic Resonance Imaging

As described above for susceptibility-weighted imaging, the signal in an MRI study can be made sensitive to the presence of reduced iron in deoxyhemoglobin. In regions of hemorrhage, the effects are striking. However, more subtle effects can also be detected in the case of changes to intravascular deoxyhemoglobin concentration. For example, when neuronal firing rates increase in an area of brain because of activation by a task, local blood flow increases while local oxygen utilization changes very little. As a result, local deoxyhemoglobin levels fall, and this reduction is detectable as a small (on the order of a few percent) increase in the signal intensity on susceptibility-weighted images. This contrast forms the basis of functional MRI, in which susceptibility-weighted images are obtained before, during, and after a subject performs a task. The MR signal in these studies is referred to as blood oxygenation level dependent, or BOLD, signal. Areas of neural activation can be detected as areas of increased BOLD signal intensity during performance of the task. One might be forgiven for thinking that this particular approach is not very useful for studying neonates, who are not particularly adept at performing tasks on demand, but there is a variant of this method that can be used to identify neural networks in the resting, or even sleeping, subject. While the precise neurophysiologic basis of this method is not yet completely understood, it is probably related to spontaneous, gradual changes in local neuronal firing rates. These changes take place over tens of seconds or minutes and are associated with matching changes in local BOLD signal. If two brain regions are connected, these gradual changes in firing rate, and hence changes in BOLD signal intensity, take place synchronously. As a result, one can identify brain regions that are connected by searching for areas that have synchronous spontaneous fluctuations in BOLD signal. Conversely, areas that have an inhibitory connection show anticorrelated fluctuations in BOLD signal. This method can be used in preterm neonates to monitor the emergence of neural networks (Fig. 63.24). While functional connectivity MRI is not in routine clinical use and requires specialized data acquisition and software, studies have shown widespread alterations in neural networks in preterm neonates at term equivalent age despite normal conventional images (Smyser et al., 2016).

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is analogous to the pulse oximetry that is commonly used in clinical practice to monitor

• **Fig. 63.24** Resting State Functional Magnetic Resonance Imaging Data From Neonates at Various Postmenstrual Ages. A seed point was placed in the motor cortex (bright yellow dot). The connections between motor cortex, contralateral motor cortex (arrow) and supplementary motor cortex (arrowhead) emerge at approximately 38 weeks' gestation. (Adapted from Smyser CD, Inder TE, Shimony JS, et al. Longitudinal analysis of neural network development in preterm infants. *Cereb Cortex.* 2010;20:2852–2862.)

arterial oxygen saturation. Both pulse oximetry and NIRS use similar wavelengths of light. For pulse oximetry, the signal is processed to isolate the signal from arterial blood to measure arterial oxygen saturation. Localization is not particularly crucial in this case and is achieved by passing the light through a digit using a pair of optodes. Commercially available NIRS devices work very similarly to pulse oximetry. Since the signal is not usually processed to evaluate arterial blood, NIRS typically provides a relative measure of mixed venous tissue oxygenation. For research applications such as functional activation, localization to various brain regions may be achieved using optode arrays (Gregg et al., 2010; Liao et al., 2010). The parameters available from NIRS include oxyhemoglobin and deoxyhemoglobin levels, cerebral oxygen saturation, and the fraction of tissue oxygen extraction (this last parameter is calculated

in conjunction with arterial oxygen saturation levels obtained with pulse oximetry). While NIRS is not widely used in clinical practice, it has been used to study a variety of conditions, including infants with apnea and bradycardia (Petrova and Mehta, 2006), different modes of ventilation (Schwaberg et al., 2015; Guerin et al., 2016), IVH (Vesoulis et al., 2016), and extracorporeal membrane oxygenation (Liem et al., 1995). In a study of asphyxiated neonates, higher cerebral oxygen saturation and lower fractional cerebral tissue oxygen extraction after 24 hours were associated with poor neurodevelopmental outcome, suggesting secondary energy failure in these neonates (Toet et al., 2006).

Neonatal Neuromuscular Disorders

NIRANJANA NATARAJAN AND CRISTIAN IONITA

KEY POINTS

- Evaluation of neonatal hypotonia includes neuromuscular conditions, and the diagnostic work-up should be approached in a stepwise manner.
- A normal creatine phosphokinase (CPK) does not completely rule out muscle disease.
- Electromyography (EMG) is useful in the diagnostic evaluation of hypotonia and weakness.
- The search for a genetic diagnosis is crucial in patients with neuromuscular disease.

Neonatal Neuromuscular Disorders

Neuromuscular disorders comprise diseases of the muscle (congenital myopathies and muscular dystrophies), neuromuscular junction (myasthenia gravis and congenital myasthenic syndromes), nerves (neuropathies), and anterior horn motor neurons (spinal muscular atrophies). They present in the neonatal period as floppy infant syndrome with or without contractures. Respiratory insufficiency and swallowing difficulties can be in the forefront of the clinical picture and are frequently associated with significant hypotonia and weakness.

This chapter reviews our current knowledge of neuromuscular disorders with neonatal onset and their clinical details alongside pathologic, genetic, and radiologic aspects as applicable. Finally, an approach to the diagnostic evaluation of neonates when a neuromuscular disorder is suspected is discussed.

Primary Muscle Disorders

Disorders of the muscle present in the early neonatal period with hypotonia or weakness. Primary muscle disorders can be subdivided into two categories: (1) muscular dystrophies and (2) congenital myopathies. Muscular dystrophies apparent in the early neonatal period or first few months of life are collectively referred to as “congenital muscular dystrophies” (CMDs). There are histopathologic differences between CMDs and congenital myopathies; CMDs demonstrate dystrophic changes on muscle biopsy, with disruption of the muscle fiber and its architecture, while congenital myopathies may have rather subtle changes such as fiber-type disproportion with preservation of the muscle fiber architecture.

Historically, classification of these disorders has been derived by histopathology. More recently, discovery of genetic defects has

led to increasing heterogeneity in the presentation of disorders. With this, newer schemas classify based on pathology and genetic findings.

Congenital Muscular Dystrophies

CMDs comprise a heterogeneous group of disorders characterized by a dystrophic process to the muscle on histopathology. With recent advancements in genetics, we are learning that many of the genetic mutations associated with CMDs may also present as congenital myopathies. Previously, CMDs were classified by the presence or absence of merosin on histopathology. Merosin, an extracellular matrix protein, was originally described as absent in one-third to one-half of cases of CMD (Dubowitz, 1994; Tome et al., 1994; Philpot et al., 1995) and can be associated with structural brain abnormalities (Philpot et al., 1999; Mercuri et al., 2001; Muntoni and Voit, 2004). Over the past decade, the advancement of genetics has allowed distinct clinical forms to be recognized, fostering a better understanding of this group of disorders.

Classification schemas alongside diagnostic approaches have been proposed that take into account this expansion of knowledge (Muntoni and Voit, 2004; Mercuri and Muntoni, 2012; Bonnemann et al., 2014). Given the numerous genes discovered and the ongoing expansion of causative genes, the CMDs have most recently been separated into seven subtypes of disorders: α -dystroglycanopathies, laminin α_2 -related dystrophy, *LMNA*-related dystrophy, collagen VI-related dystrophy, *SEPN1*-related myopathy, *RYR1*-related myopathies, and CMD without a genetic diagnosis (Bonnemann et al., 2014). *SEPN1* and *RYR1*, which are typically considered myopathies, are included in this classification scheme secondary to the varying phenotype at presentation.

α -Dystroglycanopathies

α -Dystroglycanopathies exhibit hypoglycosylation of α -dystroglycan (DG) on the cellular membrane of the muscle. The phenotype is extremely variable, with mild to severe clinical outcomes and subtypes that have significant brain involvement. More severe presentations include those of Walker–Warburg syndrome, muscle–eye–brain (MEB) disease, and Fukuyama congenital muscular dystrophy. The milder end of the spectrum includes individuals presenting in adulthood with limb girdle muscular dystrophies without brain or eye involvement.

DG is encoded by a single gene, *DAG1*, and is cleaved into two proteins, α -DG and β -DG. α -DG is an extracellular peripheral membrane glycoprotein that anchors to the cell membrane by

binding to a transmembrane protein, β -DG. α -DG also binds with high affinity to the extracellular matrix component laminin (Endo, 2015). Dystroglycanopathies are secondary to defective DG glycosylation because of mutations in a number of genes.

The number of genes involved in dystroglycanopathies have continued to increase and, to date, include at least seven genes; the first six are more frequently recognized (Kobayashi et al., 1998; Brockington et al., 2001; Yoshida et al., 2001; Beltran-Valero de Bernabe et al., 2002; Longman et al., 2003; van Reeuwijk et al., 2005a, 2005b; Roscioli et al., 2012; Willer et al., 2012; Buysse et al., 2013):

1. Protein *O*-mannosyl transferase 1 (*POMT1*; online Mendelian inheritance in man [OMIM] 607423)
2. Protein *O*-mannosyl transferase 2 (*POMT2*; OMIM 607439)
3. Protein *O*-mannose 1,2-acetylglucosaminyltransferase 1 (*POMGnT1*; OMIM 606822)
4. Fukutin (*FCMD*; OMIM 607440)
5. Fukutin-related protein (*FKRP*; OMIM 606596)
6. *LARGE* (OMIM 603590)
7. Isoprenoid synthase domain-containing protein (*ISPD*; OMIM 614631)

Studies on large populations of patients have shown that the reported mutations do not detect many of the patients with a clinical examination suggestive of an α -dystroglycanopathy, suggesting that there remain unknown genes (Mercuri et al., 2009). Clinical signs of patients include relative hypertrophy of the lower extremities, with wasting of the upper extremities and brain involvement. As genetic mutations have been found, the heterogeneity present with phenotypes has become increasingly apparent (Mercuri et al., 2006, 2009; Clement et al., 2008).

Below, three classic forms of α -dystroglycanopathies are discussed: Walker–Warburg syndrome, MEB disease, and Fukuyama congenital muscular dystrophy.

Walker–Warburg Syndrome

Walker–Warburg syndrome (WWS) is the most severe form of CMD with central nervous system (CNS) involvement. Neonatal hypotonia and severe weakness are accompanied by encephalopathy and poor vision. Ocular defects include retinal dysgenesis, microphthalmia, and anterior chamber malformations (Dobyns et al., 1989). Brain malformations include type II lissencephaly, which results in a cobblestone microgyric appearance to the cortex as well as dysmyelination of the white matter. Cerebellar malformations are also frequently present (Dobyns et al., 1989).

Infants may be thought to have CNS malformations alone; however, creatine phosphokinase (CPK) is markedly elevated. Initially, WWS was associated primarily with *POMT1* but has since been associated with the other dystroglycanopathy genes.

Muscle–Eye–Brain Disease

MEB disease typically presents at birth or in the first few months of life with hypotonia and weakness and, when compared with WWS, will have a milder phenotype of ocular abnormalities; these may not be determined until the first few years of life (Santavuori et al., 1989). Brain magnetic resonance imaging (MRI) reveals disorders of neuronal migration due to type II lissencephaly, such as pachygyria or polymicrogyria. Other associated imaging findings include cerebellar hypoplasia and white matter changes (Fig. 64.1). Initially, the *POMGnT1* gene was thought to be causative (Yoshida et al., 2001), but with time, all other reported dystroglycanopathies

have been associated with MEB as well (Mercuri et al., 2006; Godfrey et al., 2007; Clement et al., 2008).

Fukuyama Congenital Muscular Dystrophy

Fukuyama congenital muscular dystrophy, similar to other α -dystroglycanopathies presenting in the neonatal period, has clinical signs of hypotonia as well as weakness, poor feeding, and poor suck. Joint contractures may be present. CNS abnormalities are present, with cobblestone lissencephaly, pachygyria, or polymicrogyria and white matter changes. As compared to WWS and MEB, Fukuyama congenital muscular dystrophy often has more severe muscle involvement with lesser ocular manifestations. *FKTN*, with its gene product fukutin, is the only reported cause (Kobayashi et al., 1998). Fukuyama congenital muscular dystrophy has been classically described in Japanese populations (Fukuyama and Ohsawa, 1984); however, founder effects in *FKTN* have been reported in the Ashkenazi Jewish and Korean populations (Chang et al., 2009; Lim et al., 2010), with case reports in various other populations.

Other α -Dystroglycanopathies

A high suspicion for α -dystroglycanopathies should arise in any neonate with structural CNS abnormalities that involve cobblestone lissencephaly or pachygyria/polymicrogyria or when associated with ocular findings or clinical weakness. CPK will be significantly elevated in nearly all cases.

LAMA2-Related Muscular Dystrophy

LAMA2-related muscular dystrophy is a cause of severe hypotonia in infancy and has been previously referred to as merosin-deficient CMD. It is secondary to a defect in *LAMA2*, which encodes for laminin α_2 , thus resulting in the newer and favored terminology of *LAMA2*-related muscular dystrophy (Hara et al., 2011). Laminin α_2 is a constituent of merosin, which is a heteromer of α_2 , β_1 , and γ_1 subunits; absence of laminin α_2 thus results in a deficiency of merosin. The term *merosin-deficient congenital muscular dystrophy* has fallen out of favor as it is not specific to the disease etiology and can also be histologically true of some dystroglycanopathies by an indirect effect.

Clinically, *LAMA2*-related muscular dystrophy may present in the neonate with severe hypotonia and weakness or within the first 6 months of life. Contractures may be present at birth, as well as a weak cry and respiratory failure. Neonates with *LAMA2* mutations typically have muscle involvement without significant encephalopathy; however, white matter abnormalities develop in nearly all patients (Ibrahim Abdulla et al., 2007; Kumar et al., 2014).

Suspicion for *LAMA2* mutations should exist in neonates with significant hypotonia and/or contractures in the setting of respiratory failure, without significant encephalopathy or ocular abnormalities. CPK levels in infancy and early childhood are elevated, often four to five times above normal limits (Oliveira et al., 2008). On histopathologic examination, muscle biopsy will demonstrate decreased or absent binding to laminin α_2 . Care for patients with *LAMA2* mutations is supportive in nature.

Congenital Myotonic Dystrophy

The congenital form of myotonic dystrophy presents differently from the childhood or classical adult phenotype. Neonates with

• **Fig. 64.1** Brain Magnetic Resonance Imaging Changes Associated With Dystroglycanopathies. Images from a patient with *POMGnT1* mutation. T2 axial (A) and coronal (B) images demonstrating cobblestone lissencephaly, white matter changes, and parietal lobe porencephaly. T2 sagittal FLAIR (C) demonstrating porencephaly and kinked brainstem. (D) Three-dimensional rendering of cobblestone lissencephaly. (Courtesy of Dr. Francisco Perez, MD PhD.)

congenital myotonic dystrophy are often noted in utero to have complications of polyhydramnios and reduced fetal movement and may deliver prematurely. At birth, signs of hypotonia and weakness are present. Talipes equinovarus, or bilateral fixed ankle contractures, are present. Facial features include facial diplegia with a “carp” mouth appearance and bilateral ptosis. Clinical examination demonstrates hyporeflexia or areflexia and diffuse weakness more severe in distal muscles than proximal ones. Grip and percussion myotonia are not present at this age and develop in childhood. Difficulty in management of secretions is common, as is weak suck with feeding difficulties, often necessitating nasogastric tube feeds. Often, neonates may present in respiratory failure or develop it in the first weeks of life. This is secondary to muscle weakness in the inspiratory and expiratory respiratory muscles, resulting in shallow breaths. In utero, this may result in pulmonary hypoplasia. These factors lead to high mortality in the neonatal intensive care unit (NICU), which is estimated at 25%–40% of cases (Reardon et al., 1993; Campbell et al., 2004; Wallgren-Pettersson et al., 2004a). The duration and severity of the respiratory muscle weakness and pulmonary hypoplasia are

key determinants of outcome. Prolonged mechanical ventilation, defined as greater than 4 weeks in duration, is a negative prognostic factor in these neonates (Rutherford et al., 1989).

The diagnosis of congenital myotonic dystrophy should be considered when there is a positive family history. The disease is transmitted by mother and shows anticipation. A detailed history and examination of the mother often reveals characteristic facial features associated with classical myotonic dystrophy, including frontal balding, ptosis, facial diplegia, temporal wasting, or cataracts. In addition, examination of the mother typically reveals grip myotonia. These symptoms are often subtle, such that the mother is unaware of her diagnosis.

Electrographic or clinical myotonia is not present in the neonatal period. The diagnosis is often suspected on the clinical basis and by examination of the mother and then confirmed by genetic studies. The *DMPK* gene, located at chromosome 19q13.3, contains a cytosine–thymine–guanine (CTG) trinucleotide repeat in the 3′ noncoding region (Mahadevan et al., 1992). Unaffected individuals have between 5 and 27 repeats, while patients with a classical presentation have 50–1000 repeats. Anticipation is present with

this area, as the expansion increases and becomes more unstable in later generations, resulting in earlier and more severe presentation. Neonates with congenital presentation have greater than 1000 CTG repeats, with disease severity associated with number of repeats (Tsiflidis et al., 1992).

Neonates who survive the neonatal period typically require ongoing respiratory support and can survive into adulthood with close respiratory and cardiac monitoring and with therapy; however, cognitive impairment is frequent and can be severe (Echenne et al., 2008).

Other Forms of Muscular Dystrophies

Other forms of muscular dystrophies, such as Duchenne muscular dystrophy, present in early childhood with onset of weakness and calf pseudohypertrophy. Newborns who later develop Duchenne muscular dystrophy are found to have very high CPK levels in the neonatal period and in the absence of any weakness. *LAMA2* deficiency, which can present in the neonatal period, can be first noted in childhood to early adulthood with varying severity as a limb girdle muscular dystrophy.

The *LMNA* gene, which is associated with Emery–Dreifuss syndrome in older children or adults, has been found in neonates and children with CMD (Mercuri et al., 2004; D’Amico et al., 2005; Quijano-Roy et al., 2008). *LMNA* encodes for lamin A/C, which is a nuclear envelope protein. The syndrome is classically described as reduced fetal movements, severe hypotonia, and weakness with a “dropped head” appearance because of involvement of the neck muscles (Quijano-Roy et al., 2008).

Type VI Collagen-Related Disorders

Collagenopathies affecting type VI collagen may present in the neonatal period or early infancy with CMD with the eponym Ullrich muscular dystrophy and a severe phenotype or with a milder phenotype, Bethlem myopathy. Genes identified with this disorder are *COL6A1*, *COL6A2*, and *COL6A3*. The prevalence of collagen type IV disorders is not completely known; however, it is thought to be most common in the North American population and second to Fukuyama muscular dystrophy in Japan (Bonnemant, 2011).

Clinically, neonates with the Ullrich muscular dystrophy phenotype will have significant hyperlaxity, especially of the distal joints, transient kyphosis, and prominent calcanei. Joint contractures and clubfoot may be present. Skin is pliable and hyperkeratosis pilari is present by infancy.

Congenital Myopathies

The term *congenital myopathies* refers to muscle disorders that present in neonates or early infancy without dystrophic changes on muscle biopsy. Congenital myopathies tend to have a slowly progressive or nonprogressive course. In fact, some patients with congenital myopathies may improve with age. The group of congenital myopathies were described initially based on histopathologic findings on muscle biopsy. As genetic knowledge has expanded, our understanding of congenital myopathies has changed; we have learned that specific gene mutations may present as different histopathologic phenotypes (Sewry et al., 2008). Congenital myopathies may present in the neonatal period but also throughout childhood. Histology can demonstrate nemaline myopathy, central core disease, myotubular myopathy, and minicore disease.

The typical neonate presents with floppiness, weakness, and facial hypotonia and can have contractures. There is a risk for respiratory failure because of weak respiratory muscles including the diaphragm. When compared with muscular dystrophies, CPK may be normal or mildly elevated. Electromyography (EMG) may be normal or show mild myopathic changes. Thus muscle biopsy is often the next step and, in addition to genetic testing, may lead to a definitive diagnosis.

Nemaline Myopathy

Nemaline myopathy derives its name from “nema” the Greek for thread. The muscle biopsy shows threadlike rods. The rods stain red on Gomori trichrome, giving its characteristic appearance. Nemaline myopathy can present throughout the life span with varying severity. Two basic presentations may occur neonatally. Newborns may present with significant hypotonia with weakness including bulbar involvement. The facial and axial muscles are involved. Neonates may require respiratory support because of weak respiratory muscles, frequent suctioning, and nutritional support with either feeding tubes or gastrostomy tube. In more severe forms, the pregnancy history is often notable for reduced fetal movements and polyhydramnios, and the neonate has arthrogryposis at birth with severe respiratory failure and feeding difficulties in addition to immobility (Romero et al., 2013). The term *fetal akinesia* syndrome is used in patients with nemaline rod myopathy who have this more severe form, and dysmorphic features may also be present.

Those patients affected with fetal akinesia presentation or the severe congenital form have a poor prognosis; often, no improvement is seen in respiratory function or weakness over the first several months of life. Those with the milder presentation show ongoing improvement and, with time, some will learn to ambulate. However, many may still require respiratory assistance because of nocturnal hypoventilation and may have failure to thrive or scoliosis.

Eight genes have been connected to nemaline myopathy, seven of which may present in the neonatal period: nebulin (*NEB*), skeletal muscle α -actin (*ACTA1*), slow α -tropomyosin (*TPM3*), β -tropomyosin (*TPM2*), slow troponin T (*TNNT1*), cofilin 2 (*CFL2*), and Kelch-like family member 40 (*KLHL40*) (Romero et al., 2013). Nebulin accounts for up to 50% of cases, and a range of phenotypes are reported (Wallgren-Pettersson et al., 2004b).

Core Myopathies

Central core and multiminicore diseases together comprise the “core myopathies” and are the most common myopathies across all age ranges (Jungbluth et al., 2011). Histopathologically, the two are grouped together as “core” disorders, given the pattern on Gomori trichrome stain. Because of focal decreased oxidative activity from the muscle disease, there is absence of oxidative stain on muscle biopsy. Based on this visual appearance, core diseases are classified as central core, multicore, minicore, or multiminicore.

Clinically, patients with central core disease may present across the life span and neonatally are distinct, with proximal greater than distal weakness and variable bulbar involvement (Malicdan and Nishino, 1993; Jungbluth et al., 2011). Clinical features at birth may include scoliosis, contractures, and the need for respiratory support; in the most severe neonatal cases, fetal akinesia syndrome may result (Romero et al., 2003). Serum CPK is often normal or mildly elevated.

The most common gene associated with central core disease is the *RYR1* gene; this encodes the ryanodine receptor, which is a calcium channel on the sarcoplasmic reticulum (Ferreiro et al., 2002; Jungbluth et al., 2002). The ryanodine receptor and mutations in *RYR1* may also result in malignant hyperthermia. Because of phenotypic variability, it remains uncertain which patients will have this susceptibility, thus necessitating caution in all affected individuals. Mutations in the *RYR1* gene may also result in phenotypes consistent with multiminicore myopathy on histology or even nemaline myopathy (Snoeck et al., 2015).

Multiminicore disease is rare in the neonatal period and, when present, is notable for marked axial weakness, myopathic facies, and respiratory failure. A portion of older patients may present with ophthalmoplegia, which is apparent in approximately 10% of neonates with multiminicore disease. Patients with a prenatal onset of multiminicore disease may present with arthrogryposis multiplex congenita because of decreased fetal movement secondary to muscle weakness.

Two genes are frequently associated with multiminicore disease. *SEPN1*, which encodes selenoprotein 1, accounts for the majority of patients (Ferreiro et al., 2002a). Selenoprotein 1 is also associated with rigid spine disease, suggesting that the two disorders are allelic. The next most common is the *RYR1* gene (Ferreiro et al., 2002b), which is also associated with central core disease, as noted above.

Myotubular (Centronuclear) Myopathy

Centronuclear myopathy, also referred to as myotubular myopathy, is a rare neonatal cause of weakness. The name comes from the histopathologic appearance of numerous centrally located nuclei in the muscle fibers (Heckmatt et al., 1985; Jungbluth et al., 2008). Presentation in neonates is notable for severe hypotonia with bulbar involvement, including extraocular muscle weakness and myopathic facies. Respiratory compromise with need for ventilation may be present (Heckmatt et al., 1985). Given the severity of involvement, congenital myotonic dystrophy is often considered as well, and thus a good family history and examination of the mother may aid in diagnosis. Neonates may be macrosomic or have undescended testes, which may aid in diagnosis. The *MTM1* gene, encoding for myotubulin, is located on the X chromosome at Xq28, thus resulting in the male predilection for this disease. However, secondary to abnormal X-inactivation, females may be affected in the setting of this mutation (Dahl et al., 1995).

Autosomal recessive mutations may also result in disease, with similar clinical features such as bulbar involvement, severe facial weakness with ptosis, and ophthalmoplegia (Wallgren-Pettersson et al., 1995). Mutations in *BIN1* and *DNM2*, encoding for

amphiphysin-2 and dynamin-2, respectively, may also result in disease, as can autosomal recessive mutations in *RYR1* (Jungbluth et al., 2007, 2008; Snoeck et al., 2015).

Outcomes from this disorder are highly dependent on the degree of respiratory support required, and clear prognostic factors are not established, thus necessitating individual consideration. Neonates with the X-linked form tend to have a more difficult course and may not survive the neonatal period; however, phenotypic variability is present (Barth and Dubowitz, 1998).

Motor Neuron Disorders

Motor neuron disorders comprise a group of genetic disorders that share involvement of the anterior horn motor neurons. This group is dominated by 5q spinal muscular atrophy (SMA), the most common inherited motor neuron disorder. A substantial number of other rare forms of motor neuron disease are characterized; the more common ones will be mentioned below.

5q Spinal Muscular Atrophy

5q SMA is an autosomal recessive disorder with an incidence of approximately 1 in 10,000 live births (Ogino et al., 2002). Onset and severity fall along a wide spectrum, from very severe cases with intrauterine onset, to mild cases with onset in adult years and mild disability. Given the wide variability, SMA is classified into three major types depending on severity and age of onset. Some authors recognize, in addition to the three main types, one additional type: SMA type 0. The majority of patients have a homozygous deletion of the *SMN1* gene. The great variability in clinical phenotype is secondary mainly to the number of *SMN2* copies that each individual carries. The *SMN2* gene is almost identical to *SMN1* and produces principally a truncated, nonfunctional protein as well as a small amount of functional protein. More *SMN2* copies correlate with the milder phenotype (Table 64.1). All patients undergo a course that includes a decline phase followed by a plateau phase. The decline phase occurs in utero for SMA type 0 newborns affected at birth. For infants whose onset is after birth, a period of normal development is followed by a decline phase that usually lasts for weeks to months.

SMA type 0 neonates have onset of weakness in utero and often are noted to have arthrogryposis. Respiratory distress at birth is the norm and facial weakness can be present in addition to profound hypotonia and limb muscle weakness. Most of these patients die in the first weeks of life. SMA type 1 or Werdnig–Hoffman disease presents between birth and 6 months of age. Some of these neonates become symptomatic soon after birth, while others become weak after a few months of more or less normal development. Typical

TABLE 64.1 Spinal Muscular Atrophy Types

| Spinal Muscular Atrophy (SMA) Type | <i>SMN2</i> Gene Copy Number | Age of Onset | Maximal Motor Milestone Reached | Natural Course |
|------------------------------------|------------------------------|-------------------|---------------------------------|---|
| SMA type 0 | 1 | In utero | None | Fatal in the first month of life |
| SMA type 1 | 2 | Birth to 6 months | None | Fatal in the first 2 years of life |
| SMA type 2 | ≥3 | 6–18 months | Sit independently | Severe morbidity and often shortened life span |
| SMA type 3 | ≥3 | >18 months | Walk independently | Moderate morbidity and possibly shortened life span |

patients have profound hypotonia and severe weakness. Weakness is more severe in the legs than arms. Proximal muscles are weaker than distal ones. Usually there are no antigravity movements of the more proximal limb muscles with some movements distally at the level of ankles/wrists or fingers/toes. Deep tendon reflexes are unobtainable, and the face is spared. In fact, these infants tend to have a very bright facial expression. Various degrees of respiratory insufficiency are present at the time of diagnosis. Worsening of respiratory function over time is the norm, with progression to full-time respiratory support frequent. Because of the disproportionate involvement of the intercostal muscles and relative sparing of the diaphragm, a “bell-shaped” chest conformation is noted. Tongue fasciculations are often present and should be sought for. Bulbar weakness is present in essentially all type 1 SMA patients, and it manifests with swallowing difficulties, choking, and poor feeding. Contractures are not part of the typical presentation of SMA, although they can develop after prolonged immobilization.

Diagnosis is usually straightforward. Once the typical clinical picture is recognized and CPK testing is normal or minimally elevated (up to 500 IU/L), genetic testing is the next step. Ninety-five percent of patients with SMA will have a homozygous deletion of the *SMN1* gene. The rest of the patients will be found to have a point mutation on one of the alleles, while the second allele is deleted. For the latter group, *SMN1* gene sequencing will be necessary to confirm the diagnosis. Many commercial laboratories offer, in addition to confirmatory SMA testing, a *SMN2* copy number that can be helpful in staging and prognosis. The majority of type 1 SMA patients have two copies of *SMN2*. Of note, CPK, while usually normal, can in rare cases be mildly elevated but at no higher than 500 IU/L. In the era of genetic testing, the role of muscle biopsy and EMG has diminished. When available, EMG can be a speedy way to confirm the diagnostic suspicion, especially if therapeutic decisions cannot wait until genetic testing returns. A muscle biopsy is reserved for atypical cases nowadays.

Management of patients with type 1 SMA remains supportive at this time (Iannaccone, 2007). However, clinical trials are ongoing, with approval of nusinersen by the FDA in December 2016, and other drugs may soon become commercially available. Agents that are currently in clinical trials include neuroprotective agents that target the *SMN2* gene with the purpose of increasing the production of the functional SMN protein as well as gene therapy (Arnold and Burghes, 2013). Preliminary results on nusinersen, which increases functional SMN protein and is more effective, is started early in the disease course. Hence, there is interest in including SMA in the newborn screen, given the importance of early treatment if diagnosed. Despite advances in management of these patients in the last two decades, type 1 SMA (especially with onset in the neonatal period) remains a devastating disease, often with a fatal course. Most type 1 SMA patients succumb within the first 2 years of life unless aggressive respiratory intervention is offered. We now care for many type 1 SMA children who have survived through aggressive respiratory and gastrointestinal management. Their quality of life remains a major concern. The choice of aggressive, life-maintaining therapies versus palliative care raises many ethical questions and debates and, until therapies that will modify the natural history of the disease are available, will continue to do so. The help of a neuromuscular specialist can be invaluable in order for parents to make informed decisions. If aggressive treatment is chosen, the two main areas requiring early support are respiratory and gastrointestinal function. Respiration is preferably supported via noninvasive means in the form of bilevel positive airway pressure (BiPAP), although, not infrequently, some of these infants require a tracheostomy and full-time ventilator

support. Infants with SMA type 1 have poor cough and Cough Assist has proven a very important tool in airway clearance. Consultation with a pediatric pulmonologist with experience in SMA management is necessary and should be initiated early on. Essentially all SMA type 1 patients with onset of symptoms in the first month of life will have significant swallowing difficulties, leading to recurrent aspiration and poor calorie intake. Gastrostomy tube placement and Nissen fundoplication performed early on are essential. Orthopedic complications such as scoliosis occur later. Noninvasive means of ventilation and a gastrostomy tube are often part of the palliative care plan as well.

Non-5q Spinal Muscular Atrophies

Non-5q SMAs comprise a genetically and phenotypically heterogeneous group of disorders that share motor neuron involvement. Different classifications are used, including mode of inheritance and pattern of muscle involvement. Some of these disorders are important entities for neonatologists, while others are not seen in newborns. The more important disorders that have neonatal presentation are addressed below.

Spinal Muscular Atrophy With Respiratory Distress

Spinal muscular atrophy with respiratory distress (SMARD) represents a group of motor neuron disorders that present at birth and share a number of distinguishing clinical features. These conditions are characterized by a rather sudden and severe respiratory insufficiency that leads to a requirement for ventilatory support as well as predominantly distal weakness and distal contractures. Respiratory insufficiency can be present at birth (suggesting an in utero onset) or develop in the first 6 months of life. Diaphragmatic weakness leading to diaphragmatic eventration is characteristic. These features differ from the relative diaphragmatic sparing and predominantly proximal weakness seen in 5q SMA. A number of genes have been identified so far. SMARD1, the better known form of SMARD, is an autosomal recessive disease caused by mutations in the *IGHMBP2* (immunoglobulin μ -binding protein 2) gene. SMARD2, an X-linked disease caused by mutations in the *LASIL* gene, has been described more recently (Butterfield et al., 2014). Both genes seem to play a role in ribosome biogenesis. Other genes are likely to be discovered. The management is supportive. Restrictive lung disease is the main cause of morbidity and mortality. Swallowing difficulties, aspirations, and poor caloric intake are also common, leading to gastrostomy tube placement. Cognitive development is believed to be normal. Palliative care is often offered for the more severe cases, while milder cases may benefit from aggressive respiratory and gastrointestinal management. Late-onset forms with a milder phenotype have also been described.

X-Linked Infantile Spinal Muscular Atrophy

X-linked infantile spinal muscular atrophy (XL-SMA) is a recently described motor neuron disease characterized by arthrogryposis, hypotonia, proximal weakness, facial weakness, and respiratory failure. XL-SMA has been found to be associated with hemizygous mutations in the *UBE1* gene (Ramser et al., 2008). The disease is usually fatal in the first 2 years of life. Management is supportive.

Pontocerebellar Hypoplasia Plus Spinal Muscular Atrophy

Pontocerebellar hypoplasia (PCH) is a heterogeneous group of inherited disorders that share hypoplasia or atrophy of the cerebellum and pons. Other CNS abnormalities are common. PCH type 1

has, as distinguishing features, muscle weakness and hypotonia caused by a motor neuron disease. So far mutations in three genes are identified as causing type 1 PCH: *VRK1*, *EXOSC3*, and *EXOSC8* (Renbaum et al., 2009; Wan et al., 2012; Boczonadi et al., 2014). All are inherited in an autosomal recessive pattern. Although the severity and age of onset varies, many of these patients present in the neonatal period with hypotonia, weakness, contractures, and respiratory distress as well as encephalopathy. Survival ranges from a few months to a few years. Management is supportive. Genetic diagnosis is important for family planning.

Transient Neonatal Myasthenia Gravis

Approximately 10%–15% of newborns born to mothers with autoimmune myasthenia gravis develop a transient form of myasthenia gravis. The disease results from passive transfer of antibodies and leads to fatigable weakness, including weakness of the respiratory and swallowing muscles. Supportive treatment is necessary for a brief duration of time (days to weeks), until the antibody titers decline and strength returns. Diagnosis is based on the presence of acetylcholine receptor (AChR) antibodies (rarely muscle-specific kinase antibodies) in newborn serum. More recently, it was recognized that some of the infants born to mothers with autoimmune myasthenia gravis have a less benign course with unexplained myopathic features, dysarthria, velopharyngeal insufficiency, and contractures. These patients may have feeding and respiratory difficulties in the neonatal period. Maternal AChR antibody status should be checked, even in the absence of symptoms, in order to prevent recurrence with future pregnancies (Hacohen et al., 2015).

Congenital Myasthenic Syndromes

Congenital myasthenic syndromes (CMS) include a growing number of heterogeneous disorders that are all characterized by the failure of neuromuscular transmission secondary to a genetic defect. A significant proportion of CMS cases present in the neonatal period or early infancy. Diagnosis is often delayed by years. The general clinical characteristics include fatigable muscle weakness involving the extraocular, bulbar, respiratory, and limb muscle systems in different combinations (Engel, 2012). Certain patterns are unusual enough to deserve special mention. *Dok7* CMS patients can present in the neonatal period with stridor due to bilateral vocal cord paralysis, respiratory distress, and feeding difficulties. Intubation and ventilator support are necessary for some patients (Jephson et al., 2010). Episodic respiratory deterioration with fatigue during feedings but otherwise little or no symptoms in between were noted in a patient with end-plate acetylcholinesterase deficiency (personal observation). Choline acetyltransferase mutations lead to hypotonia with marked bulbar symptoms and respiratory insufficiency in the neonatal period followed by life-threatening episodes of apnea later in infancy (Ohno et al., 2001). In a retrospective review of CMS cases presenting in early infancy, 8 out of 11 patients presented at birth in general with severe respiratory distress in addition to hypotonia, weakness, and contractures (Zafeiriou et al., 2004). Laboratory evaluation is usually unremarkable, with normal CPK. Muscle biopsy is either unremarkable or shows mild nonspecific findings. The importance of electrophysiologic studies, specifically repetitive nerve stimulation, is paramount in establishing the presence of a neuromuscular junction defect. Genetic testing is available commercially. Although a good number of CMS patients respond partially to pyridostigmine, patients with certain types of

CMS may worsen. Close observation is needed when pyridostigmine is administered, especially if the exact type of CMS is not known. Other medical treatments may be available, depending on the specific CMS identified. Respiratory support remains important though. Noninvasive ventilation is preferred as some patients improve with age. Nutritional support with a gastrostomy tube should be considered.

Peripheral Neuropathies

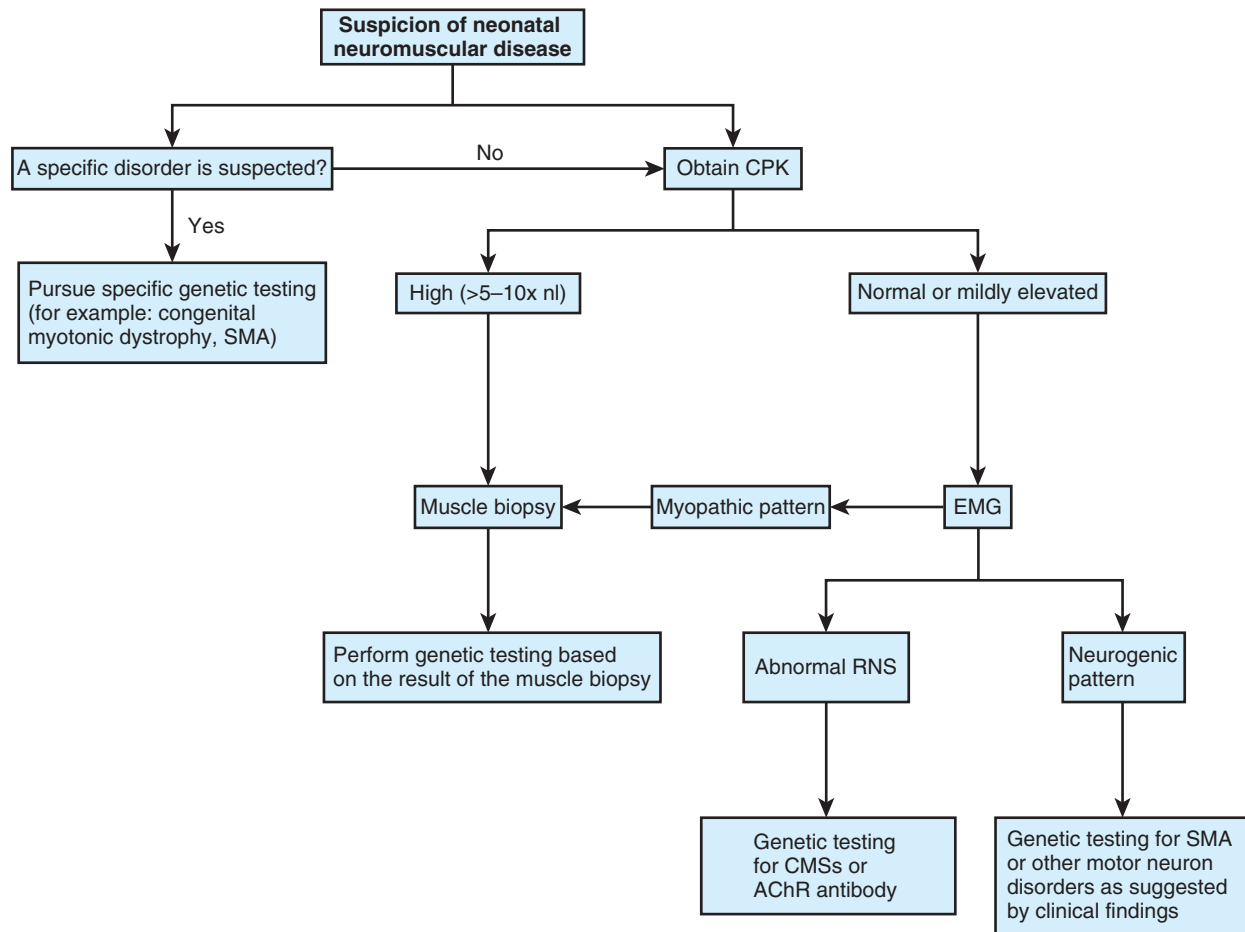

Inherited peripheral neuropathies are one of the least common causes of floppy infant syndrome in the neonatal period. The main presentations in the neonatal period are hypotonia and weakness, often with feet deformities. Respiratory difficulties may be present. Electrophysiologic studies will confirm the neuropathy and orient the genetic testing by subdividing them into axonal versus demyelinating (Baets et al., 2011). Management is supportive.

Approach to Neonatal Neuromuscular Disorders

The field of pediatric neuromuscular disorders has exploded following the genetic advances of the last two decades. While the old clinicopathologic classification remains useful, one needs to keep in mind that different genotypes can lead to the same phenotype, and the same genotype can present with different phenotypes. Many of these disorders have significant intrafamilial variability.

As in any area of medicine, a good history and physical examination, including a neurologic examination, are essential. Pregnancy evolution and complications such as polyhydramnios should be noted. A history of reduced fetal movements is important. Obstetric history may point to a hypoxic–ischemic injury as the etiology for hypotonia and weakness. Three generations of family history can identify other affected family members. One needs to keep in mind that many neuromuscular disorders may have significant intrafamilial variability. Looking for grip myotonia by shaking the mother's hand will help point the clinician toward CMD. This is something that should be done each time a newborn is evaluated for hypotonia. Physical and neurologic examination of the floppy newborn should include delineation of hypotonia (axial vs proximal vs distal vs diffuse) as well as weakness (proximal vs distal vs diffuse). The presence or absence of deep tendon reflexes, the resting position, and the amount of spontaneous movements are important.

Given the fact that the central causes of hypotonia are very common, signs and symptoms suggestive of CNS involvement should be sought. These include, but are not limited to, encephalopathy, seizures, dysmorphic features, history suggestive of hypoxic–ischemic injury, severe hypotonia in a setting of mild weakness, and metabolic derangements. A history of hypoxic–ischemic injury is not mutually exclusive for a neuromuscular condition, as many of these conditions place the newborn at risk for hypoxic–ischemic injury in and of themselves. Newborns with CMD seem to suffer superimposed hypoxic–ischemic injury relatively more frequently. Often the newborn that is floppy at birth undergoes brain and sometimes spine imaging. An MRI technique is usually preferred. In the majority of neuromuscular conditions, these studies are normal. Pontine and cerebellar hypoplasia will point in the direction of SMA with PCH. Some forms of CMD can often present with significant brain malformations, as mentioned above. The white matter changes described in merosin-deficient CMD are not apparent in the neonatal period. Brain and spine

imaging are most important in the evaluation of the central type of hypotonia.

In addition to the history and physical examination, the tools available to the clinician include:

1. CPK
2. EMG studies
3. Muscle biopsy
4. Genetic testing

Few gestalt diagnoses exist. CMD presents with typical facial features. If this is combined with maternal myopathic facial appearance and grip myotonia, one may go straight to genetic confirmation. The presentation of SMA in the neonatal period is another situation when gestalt diagnosis is possible for the experienced neonatologist. A proposed stepwise systematic algorithm for evaluation is presented in Fig. 64.2.

Creatine Phosphokinase

CPK is a rapid test that should be performed when a neuromuscular condition is first suspected. Significantly elevated values (more than 5 times normal) will point toward a muscle disorder, more likely a CMD. Normal or mildly elevated values can be seen in congenital myopathies and SMA.

Electromyography

Seen as a difficult test to perform in newborns, in the right hands, EMG can be of immense help. The main advantage of EMG is a rapid, on the spot, diagnosis of a neurogenic process versus myopathic process versus neuromuscular junction defect. When available, EMG should be offered early in the diagnostic process.

Muscle Biopsy

Despite advances in genetic diagnosis, muscle biopsy remains an important tool in the diagnosis of neuromuscular disorders. Its main utility consists in identification of particular types of congenital myopathy or CMD and, as a consequence, directing the genetic testing toward smaller panels of genes. As the pricing of genetic testing is decreasing, it is becoming feasible to start the work-up with genetic testing and employ muscle biopsy only if the first round of genetic tests fails to reveal a genetic abnormality.

Genetic Testing

The availability of genetic testing has increased exponentially in the last decade. A clinicopathologic diagnosis is no longer sufficient,

and every effort should be made for genetic confirmation. Single genes as well as panels of genes are now commercially available from multiple commercial laboratories.

Neonatal Seizures

NIRANJANA NATARAJAN AND SIDNEY M. GOSPE, JR.

KEY POINTS

- Neonatal seizures are common.
- Clinical assessment alone is insufficient for diagnosis, and ancillary tests are necessary.
- Seizures are often symptomatic of an underlying cause requiring investigation.
- Clinical decision making is divided between determining the etiology and treatment of seizures.

CONTROVERSY BOX

- The independent impact of electrographic-only seizures is uncertain. While increasing evidence suggests an effect on risk of the later development of epilepsy and neurodevelopmental outcomes, the aggressive treatment of electrographic seizures remains debated.
- First-line antiepileptic drugs (AEDs) have limited efficacy, resulting in varied provider practices and off-label use of further AEDs.
- Optimal length of treatment with AEDs after resolution of seizures varies by provider. Retrospective studies suggest shorter treatment length is sufficient.

Neonatal Seizures

Seizures in the neonate occur in 2 to 4 per 1000 live births and are a cause of neonatal morbidity and mortality (Lanska et al., 1995; Ronen et al., 1999; Saliba et al., 1999). Frequently, this onset is a neurologic emergency, requiring prompt and thorough diagnostic investigations and therapeutic interventions. Seizures in the newborn may be transient due to electrolyte abnormalities, the harbinger for underlying brain injury or abnormalities, or the initial presentation of an underlying medical disorder. The clinical appearance of seizures at this age differs from that seen in older infants and children. Seizures themselves may be subtle, or without clinical manifestations, and challenging to differentiate from other involuntary movements in the neonate.

Many dilemmas remain within diagnosis and management of neonatal seizures. Guidelines in recent years have been created to aid clinicians in how to diagnose neonatal seizures through ancillary diagnostic tests. There are ongoing efforts to determine how aggressively to treat seizures, which medications to utilize, how long to treat seizures, and the impact of neonatal seizures on neurodevelopmental outcome.

This chapter discusses the diagnosis, neurophysiologic criteria, etiologic considerations, treatment, and prognosis of neonatal

seizures. For the purposes of this chapter, the term *seizure* refers to an *epileptic event*: that is, those with electrographic correlate.

Diagnosis of Seizures

Neonatal seizures are often brief and subtle in appearance, thus raising diagnostic uncertainty when unusual movements are present. Frequently, clinical features suspicious for seizure result in initiation of treatment prior to ancillary testing. This, however, is not recommended. As newborns may have automatic or motor behaviors that mimic movements concerning for seizure, and encephalopathic newborns at high risk of seizures may develop paroxysmal movements that are nonepileptic alongside seizures, ancillary testing to aid in diagnosis is imperative to limit overtreatment as well as underrecognition of events. Medical providers of various backgrounds have been shown to have difficulty determining whether events represent seizure or not, based on clinical features alone. An observational study looking at healthcare providers' assessment of seizure identification of 20 video clips (11 were seizure, 9 were not) found that providers were correct on average 50% of the time when given history and clinical features alone (Malone et al., 2009). Additionally, identification of seizures by clinical criteria alone may underestimate the number of seizures present (Clancy et al., 1988; Murray et al., 2008).

With this in mind, the American Clinical Neurophysiology Society developed guidelines in 2011 on the use of continuous electroencephalography (EEG) monitoring in neonates (Shellhaas et al., 2011). While it is recognized that not all facilities will have the resources necessary to monitor, this guideline provides goals as to how to monitor for seizures in high-risk neonates or which neonates with suspicious events should be evaluated.

Many institutions incorporate amplitude-integrated EEG (aEEG) to aid in the detection of seizures. This tool uses two or four scalp EEG electrodes to obtain a raw tracing of information. This signal undergoes processing and time compression, creating a single channel tracing per hemisphere. The technical aspects of this approach are nicely reviewed elsewhere (El-Dib et al., 2009).

Continuous EEG and aEEG are discussed later in the Electrographic Seizure Criteria section.

Categorization of Seizures

Seizures in the neonate often are brief and subtle in nature and may present differently than seizures in older infants or children. Historically, neonatal seizures have been categorized by clinical semiology into five categories: focal clonic, multifocal clonic, tonic,

TABLE 65.1 Seizure Types

| Seizure Type | Characteristics | Nonepileptic Differential |
|--------------|---|---|
| Focal clonic | <ul style="list-style-type: none"> • Repetitive rhythmic jerking of an extremity or hemibody • There is a rapid phase and a slow phase of movement. • These movements cannot be suppressed by tactile restraint. | <ul style="list-style-type: none"> • Jittery movements, tremulousness • Nonepileptic movements tend to have equal phases of movement. |
| Focal tonic | <ul style="list-style-type: none"> • Stiffening of an extremity or hemibody | <ul style="list-style-type: none"> • Provoked bilateral stiffening • “Brainstem release phenomena” • Gastroesophageal reflux |
| Myoclonic | <ul style="list-style-type: none"> • Lightning fast jerk of a single or multiple extremities | <ul style="list-style-type: none"> • This can be epileptic or nonepileptic. |
| “Subtle” | <ul style="list-style-type: none"> • Tonic eye deviation • Head version • Chewing movements | <ul style="list-style-type: none"> • Bicycling movements • Chewing movements |

myoclonic, and subtle seizures (Volpe, 2008). Other classification schemata take into account the presence or absence of EEG correlates during clinical movements, separating movements into “epileptic” and “nonepileptic” movements (Table 65.1).

Clonic Seizures (Focal and Multifocal)

Rhythmic movements with a rapid flexor phase followed by a slower extension phase persisting despite flexion of the affected limb may represent a clonic seizure. This can be mistaken for nonepileptic phenomenon such as tremor or jitteriness in some infants. Distinguishing features between the entities include the rhythmicity of the event and its ability to be suppressed or altered by changes in positioning. Subtle but important distinguishing features include the rapidity of the flexor phase as compared with the extensor phase, as tremulousness or jitteriness tends to have symmetric flexor and extensor phases.

Focal clonic or hemiclonic seizures can be seen in neonates with injury localized to a specific site, such as a perinatal stroke or other cerebrovascular event (Clancy et al., 1985; Levy et al., 1985). Multifocal seizures, clonic seizures that arise at times from multiple locations, can be seen in neonates with multifocal or generalized brain abnormalities, such as hypoxic–ischemic encephalopathy.

Tonic Seizures

Tonic seizures are those with sustained flexion or extension of a muscle group. This can affect limbs but also the eye muscles with sustained eye deviation or the head, resulting in head version. Tonic seizures may be epileptic or nonepileptic, with bilateral tonic extension not having a correlate on EEG (Mizrahi and Kellaway, 1987). Nonepileptic tonic posturing may represent “brainstem release” in the setting of extensive cortical dysfunction. This cortical dysfunction may allow uninhibited subcortical expression to occur. Other movements that may be misidentified as tonic seizures include dystonic posturing and may coexist in neonates with seizures, especially in the setting of brain injury.

Myoclonic Seizures

Myoclonic movements are rapid, lightning fast jerks that can be focal, multifocal, or generalized in nature. Myoclonus can occur at multiple levels of the nervous system: cortical regions, brainstem,

and spinal cord. With this, myoclonus may be epileptic (myoclonic seizures) while others are not, requiring additional evaluation with neurophysiologic studies to determine the nature of the myoclonus. Myoclonus often represents underlying pathology and thus requires etiologic evaluation for metabolic, infectious, structural, and genetic causes (Scher, 1985).

In some instances, however, myoclonus is benign. In preterms, myoclonus can occur in the absence of nervous system abnormalities; however, consideration of metabolic or infectious causes is warranted when myoclonus is excessive. Healthy neonates may have exaggerated myoclonus in sleep, deemed *benign sleep myoclonus of the newborn* (Coulter and Allen, 1982).

Subtle Seizures

Subtle seizures are those with motor automatisms such as oral–buccal–lingual movements and are the most frequently seen subtype of neonatal seizures. They may be seen in conjunction with other seizure types, such as multifocal clonic or focal clonic seizures. Given their subtlety, these are notoriously difficult to determine clinically, where often one must first be cognizant of the neonate’s typical behaviors, movements, and autonomic findings and then detect unexplained alterations of these patterns. Repetitive movements such as bicycling, pedaling, as well as ocular, oral, or buccal–lingual movements are in this category. One should pay close attention to associated vital sign changes, such as otherwise unexplained fluctuations in heart rate, blood pressure, or oxygen saturation in association with this. As more benign movements may mimic these subtle seizure motor features, confirmation with EEG is recommended.

Nonepileptic Neonatal Movements

As noted previously, newborns are prone to a variety of movements that may raise suspicion for seizures but represent other neurologic or nonneurologic entities (Mizrahi and Kellaway, 1998). Given this clinical uncertainty, EEG with concurrent video is recommended to characterize the clinical event with neurophysiologic data (Shellhaas et al., 2011).

Tremulousness or Jitteriness

Tremor can be seen frequently in the neonate and can be mistaken for clonic activity by medical personnel. The phenomenology of

this movement is flexion and extension, with equal phases and amplitude of both, distinguishing this from clonic activity. Jitteriness is rhythmic tremors around a fixed axis. Repositioning of the affected limb may often decrease or extinguish the movement, as can flexion. Neonates may be alert or hyperalert, although this may be present in neonates with somnolence secondary to encephalopathy. Tremor may be asymmetric in nature and of varying amplitudes. Movements tend to be spontaneous but may occur in response to tactile stimulation.

Tremors as well as jittery movements can occur secondary to metabolic derangements such as hypoglycemia or hypocalcemia, as well as intracranial hemorrhage and growth restriction, or in hypothermia. Exposure to maternal medications such as selective serotonin reuptake inhibitors (SSRIs) or illicit substances such as cocaine and marijuana has also been associated with tremulousness. Nevertheless, these movements are common, with one study showing mild, moderate, or excessive jitteriness in 44% of healthy term infants (Parker et al., 1990).

Movements generally decrease with increasing postconceptional age, with a normal neurologic outcome (Parker et al., 1990).

Myoclonus Without Electrographic Correlate

Myoclonus is defined as a sequence of repetitive, often nonrhythmic movements, brief shock-like movements caused by sudden involuntary contraction or relaxation of one or more muscles (Sanger et al., 2010). Myoclonic movements may originate from multiple levels of the neuroaxis, as discussed previously, and may lack electrographic correlate. This nonepileptic myoclonus is more frequent in preterm newborns but also in term neonates and can be benign in some instances, while a harbinger for underlying abnormalities in others. Movements occur in neonates without encephalopathy and resolve with awakening. Benign neonatal sleep myoclonus was first described by Coulter and Allen (1982) and is considered a diagnosis of exclusion. Suspicion for this should arise when described in an otherwise healthy newborn with myoclonus that occurs in sleep and resolves with awakening and is typically arrhythmic and of varying amplitude. It may increase with attempts of physical restraint or be induced by rocking and occurs in all stages of sleep (Maurer et al., 2010). This typically resolves by 3 months of age, although some infants may have symptoms until 6 to 12 months of age (Maurer et al., 2010).

This is in contrast to myoclonus occurring in an infant with encephalopathy. In this case, myoclonus may be stimulus induced, with increased myoclonus to tactile or painful stimulation, and occurs in the setting of severe brain injury. Additional etiologic considerations in the neonate with myoclonus with encephalopathy include infection such as encephalitis or meningitis, intraventricular hemorrhage, periventricular leukomalacia, or metabolic disorders such as glycine encephalopathy (Scher, 1985). In these latter cases, the EEG background is typically abnormal and may have epileptiform discharges, although the myoclonus itself lacks epileptiform correlate (Scher, 1985). Certain medications may also produce nonepileptic myoclonus; midazolam-induced and lorazepam-induced myoclonus are reported in preterm or very low birth weight neonates (Lee et al., 1994; Magny et al., 1994; Sexson et al., 1995). If medication-induced myoclonus occurs, further use of the offending drug should be limited in the neonatal period where possible. As the response is thought to be developmental, use of benzodiazepines need not be avoided in infancy or childhood.

Dyskinesias

Dystonic and dyskinetic movements are frequent in the neonate and commonly may be mistaken for seizures. This group of movements is associated with the basal ganglia or the extrapyramidal pathways and can occur secondary to acute or chronic effects on these structures. Dystonia is the involuntary sustained or intermittent cocontraction of agonist and antagonist muscles resulting in abnormal posture (Sanger et al., 2010). In the neonate, it often represents intrapartum or antepartum injury with severe injury to the basal ganglia (Scher, 2008). Some inborn errors of metabolism may present with hypertonicity, opisthotonic posturing, or dystonia (e.g., maple syrup urine disease, monoamine neurotransmitter disorders) (Hyland, 1999; Strauss et al., 2006).

The dystonia or posturing seen reflects a functional subcortical disinhibition secondary to damage or malformation to the cortex (Sarnat, 1984). As dyskinetic and dystonic movements are frequent in encephalopathic neonates who may also have epileptic events, use of continuous video EEG is imperative to prevent misdiagnosis and inappropriate treatment of either diagnosis.

Neurophysiologic Diagnosis of Seizure

Neonatal seizures are challenging to identify clinically for a multitude of reasons, including challenges distinguishing from nonepileptic involuntary movements, overall subtlety, as discussed above, as well as the potential for seizures to electroclinically dissociate after treatment, becoming apparent only with the aid of EEG (Scher, 1994). Reports estimate that as many as 80% of seizures may be electrographic, without any clinical component (Clancy et al., 1988). The neurophysiologic definition of seizures, status epilepticus, electroclinical uncoupling, as well as the significance of interictal abnormalities are discussed below.

Because of the inability to accurately detect seizures clinically, it remains imperative to use ancillary studies to aid in the detection of seizures. Two modes of seizure detection will be briefly discussed: EEG and aEEG. There remains controversy regarding the degree to which one needs to treat electrographic-only seizures; however, there is a growing body of evidence to suggest the importance of treatment. This is discussed later in the Neurodevelopmental Outcomes section.

Electroencephalography

Conventional EEG, the gold standard for neonatal seizure detection, is an invaluable tool for seizure detection. Multiple electrodes are placed in accordance with the international 10–20 system, or with the modified neonatal montage, alongside a single electrocardiogram lead and respiratory belt. Interpretation of EEG requires mastery of the normal and abnormal patterns of term and preterm wakefulness and sleep. Aid from the EEG technologist or bedside nurse is imperative, to note potential events of concern and artifacts (such as nursing care, feeding, etc.).

Neurophysiologic Definitions

Seizures themselves have been described and characterized recently by the American Clinical Neurophysiology Society (Tsuchida et al., 2013). To be considered a seizure, rhythmic activity lasting 10 seconds with a minimum of 2μV peak-to-peak (pp) voltage that evolves in quality and subsequently resolves must be present. Events with these characteristics lasting less than 10 seconds are referred

to as *brief rhythmic discharges* (BRDs), and while they are not consistent with seizures, they pose an increased risk of developing seizures. Shorter-length studies may detect BRDs without electrographic seizures that have a high likelihood of coexisting, and thus continuous EEG monitoring is recommended to ensure appropriate recognition of seizures.

Status epilepticus, defined in older children or adults as a seizure lasting greater than 30 minutes or more than one seizure without a return to baseline in between, is not an appropriate definition in neonates, given the often comorbid encephalopathy and overall challenges in determining true return to baseline. With this, the definition of status epilepticus has been established as seizures constituting greater than 50% of an hour-long epoch, which is arbitrarily defined (Tsuchida et al., 2013).

Continuous monitoring of neonates with EEG is recommended in certain high-risk populations. These include instances where one may suspect neonatal seizures to occur, such as in acute brain injury secondary to perinatal asphyxia, in neonates with clinically suspected seizures, or when neonatal epilepsy is suspected. In some instances, it may be appropriate to continue monitoring after withdrawal of AEDs. Although seizures in the setting of acquired brain injury are not likely to recur shortly after resolution of seizures, those with neonatal epilepsy syndromes or cerebral malformations may deserve monitoring when AEDs are discontinued. It is recommended that neonates remain monitored for a 24-hour period once seizure-free.

Electroclinical Uncoupling

Administration of AEDs in the setting of electroclinical seizures can result in a phenomenon where electrographic seizures persist while the clinical manifestations resolve. This is termed *electroclinical uncoupling*. One study estimated that 25% of neonates had persistent electrographic seizures after receiving AEDs despite the resolution of clinical seizures (Scher, 1994).

This information suggests that seizures may be underrecognized without ancillary testing, resulting in the underdiagnosis and treatment of status epilepticus. The effects of undertreatment contribute to neurodevelopmental outcomes, as later discussed.

Amplitude-Integrated Electroencephalography

aEEG is a cerebral function monitor that has become available as a bedside tool more recently in the last decade in the United States. It utilizes 2 to 4 leads, typically placed over the central and parietal regions. Using sophisticated electronics, this raw signal is converted into a single channel that denotes the pp amplitude from one waveform to the next, which is then time compressed. Advantages of aEEG include bedside availability and interpretation, as well as reduced cost as compared with continuous EEG monitoring (Hellström-Westas et al., 2008). Because of the technical processing of this signal, there are limitations, including challenges in detection of brief or low-amplitude seizures or seizures that do not occur in the brain regions covered by aEEG (Shellhaas et al., 2007). During a seizure, there is a sudden and sustained increase of the lower and upper margins on aEEG, with raw EEG signal demonstrating a monomorphic waveform consistent with seizure (Hellström-Westas et al., 2008). aEEG may also be limited as it is prone to artifactual signals from movement, high-frequency oscillator ventilation, or extracorporeal membrane oxygenation (ECMO). In a recent systematic review of detection of neonatal seizure on aEEG (aEEG and a raw trace were examined simultaneously), a median sensitivity

of 76%, with a median specificity of 85%, was observed but with high variability when comparing studies (Rakshasbhuvankar et al., 2015). Consequently, it is still recommended that aEEG should be used as a screening tool where the gold standard of continuous EEG is limited but with placement of the latter when seizures are detected (Glass et al., 2013; Sanchez Fernandez and Loddenkemper, 2015).

Interictal Abnormalities

Beyond determination of seizures, EEG detects interictal findings that aid patient management. The presence of background abnormalities may be serially followed to determine the progression of an encephalopathy (Scher, 1994). While background findings may not be pathognomonic for particular etiologies, these findings in conjunction with the remainder of the diagnostic work-up (history, clinical examination, and laboratory and imaging findings) aid in the development of the overall prognosis for a patient.

Etiologies of Neonatal Seizures

Once it is determined that a neonate is having seizures, further management is divided into the treatment of seizures, discussed in a later section, as well as establishing the etiology of seizures. Neonatal seizures are not disease specific and can occur in a variety of conditions that may occur before, during, or after birth. Seizures may occur in the setting of electrolyte disturbances such as hypoglycemia, hypocalcemia, or hypomagnesemia and may respond to corrections of these. Seizures may harken underlying brain injury in the setting of hypoxic-ischemic encephalopathy antepartum injury, perinatal stroke, hemorrhage, trauma, or infection. Metabolic, genetic, or cerebral dysgenesis are additional etiologic considerations (Table 65.2).

Hypoxic-Ischemic Encephalopathy

Hypoxia-ischemia is considered the most common cause of neonatal seizures and is an important consideration in the neonate with encephalopathy and seizures. The American College of Obstetricians and Gynecologists initially published guidelines in 2004 proposing five criteria that suggest an intrapartum etiology: profound acidemia with a pH less than 7.0; Apgar score of 0 to 3 beyond 5 minutes of life; sudden sustained fetal bradycardia or absence of fetal heart rate variability; onset of multisystem disease within 72 hours; and supportive early imaging (American College of Obstetricians and Gynecologists, 2004). Given advances in knowledge over the last decade, this guideline was updated in 2014 and reflects the difficulties in determining whether an event was intrapartum and hypoxic-ischemic related or caused by another origin of neonatal encephalopathy (Executive Summary, 2014).

In the era of therapeutic hypothermia, identification of neonates who may benefit from this therapy, which is geared toward prevention of secondary energy failure and additional brain injury, includes neonates meeting laboratory criteria suggestive of hypoxic-ischemic injury, in addition to presence of moderate or severe encephalopathy (Gunn et al., 2005; Shankaran et al. 2005).

While hypoxic-ischemic encephalopathy is a common cause of neonatal seizures, it is important to recognize that injury may occur postnatally, and several antepartum and intrapartum factors carry a higher association with neonatal seizures. One study using logistic models found postnatal bleeding, placental separation, preeclampsia, cesarean section because of hemorrhage, meconium-stained fluid, and shoulder dystocia among the antepartum and intrapartum

factors associated with neonatal seizures (Patterson et al., 1989). Additional factors of diabetes mellitus, advanced maternal age over 40 years, infection, or intrapartum fever were identified in a population-based study (Glass et al., 2009a).

Other Causes of Neonatal Encephalopathy

Hypoxic–ischemic encephalopathy, however, is not the only cause of neonatal encephalopathy consisting of alteration of arousal and muscle tone. Postnatal causes reflected by placental abnormalities, or growth restriction, and factors like intrapartum fever and inflammation and infection can result in a neonatal presentation of encephalopathy with neonatal seizures.

Even in the absence of neonatal meningitis or infection, in one study, intrapartum fever was associated with a fourfold increase in early-onset seizures (Lieberman et al., 2000). Thirty-two neonates without a proximal cause of seizures and 152 controls were assessed;

neonates with seizures were more likely to have been born in the setting of intrapartum fever. It is speculated that circulating maternal cytokines resulted in physiologic events that led to neurologic injury, even in the absence of infection (Lieberman et al., 2000).

Placental findings may represent more chronic disease states, suggesting an antepartum insult in neonates with encephalopathy is not due to birth asphyxia. In one study of 73 neonates, placentas were evaluated in neonates with electrographically confirmed seizures and compared with controls without seizures. Placental lesions consistent with antepartum chronic asphyxial stress such as chronic villitis or maturational changes were increased in those infants with neonatal seizures, as compared with those without (Scher et al., 1998).

Cerebrovascular Lesions

Ischemic or hemorrhagic lesions of either arterial or venous origin are associated with a high risk of seizure in the newborn (Ment et al., 1984; Clancy et al., 1985; Levy et al., 1985; Scher and Beggarly, 1989; Rivkin et al., 1992). In term neonates with perinatal arterial stroke, seizure is the most common presentation, accounting for between 70% and 90%, followed by hypotonia or feeding difficulties (Lee et al., 2005; Grunt et al., 2015). Neonates with cerebral infarction often are otherwise healthy in appearance, with reassuring presentation, not consistent with asphyxia. Use of neuroimaging with magnetic resonance imaging (MRI) is necessary to demonstrate the focal lesion (Osmond et al., 2014; Weeke et al., 2015). Multiple factors are associated with perinatal arterial stroke in aspects affecting the maternal–fetal dyad (Lee et al., 2005).

In preterm infants, intraventricular hemorrhage (IVH) is the most common cause of seizures (Scher et al., 1993; Sheth et al., 1999). IVH is common in preterm neonates and is the cause of seizures in as many as 45% of EEG-confirmed seizures in this population (Scher et al., 1993). IVH typically occurs in the first few days after birth; it can present asymptotically, detected only on screening cranial ultrasounds obtained for this purpose. Some infants, however, will present catastrophically, with bulging fontanelle, hypertonia, apnea, and seizures (Volpe, 2008). Seizures in preterm newborns are thought to be underestimated, as studies prospectively assessing seizure frequency in high-risk preterm neonates find a higher incidence than in those where EEG is obtained in response to a clinical event (Hellstrom-Westas et al., 1991; Scher et al., 1993; Strober et al., 1997).

Seizures caused by IVH may also be present in term neonates; however, further etiologic investigations are imperative, as hemorrhagic transformation of a venous stroke or arteriovenous malformation may be present (Bruno et al., 2014).

Cerebral venous infarction may also result in neonatal seizures (Rivkin et al., 1992). This may occur in the setting of systemic infection, dehydration, or poor feeding with cerebral venous sinus thrombosis. These lesions may result in hemorrhagic transformation and be associated with IVH. In preterm infants, periventricular hemorrhagic infarctions occur within the deep white matter, also referred to as a *grade IV germinal matrix hemorrhage*, and may be complicated by seizures (Strober et al., 1997).

Infants with congenital heart defects, persistent pulmonary hypertension of the newborn, or requiring ECMO have increased risk of seizures caused by recurrent hypoxia hypotensive injury, and emboli. Persistent pulmonary hypertension of the newborn may cause severe and recurrent hypoxia and is associated with cerebrovascular lesions and seizures (Scher et al., 1986). Neurodevelopmental outcomes of neonates with congenital heart defects

are of increasing interest, given advances in cardiothoracic surgery with improved survival of these children. The occurrence of electroclinical and electrographic seizures have been noted in this population, in association with cardiac surgery requiring deep hypothermic circulatory arrest or after prolonged resuscitation (Clancy et al., 2005; Gaynor et al., 2006). In a recently published study, all neonates undergoing cardiac surgery were subsequently placed on continuous EEG monitoring. In this study, 8% of all postoperative patients had seizures, the majority of which were electrographic without clinical correlate (Naim et al., 2015). Infants with seizures had more severe in-hospital course and increased mortality.

ECMO is associated with increased neonatal brain injury and seizures. Hypotension prior to ECMO, or as a complication of ECMO support, places the neonate at risk for watershed distribution injury. The anticoagulation necessary for circuit use may convert an ischemic injury to a hemorrhagic one, with risk of edema or herniation. It is estimated that between 5% and 10% of patients develop seizures during ECMO (Mehta and Ibsen, 2013).

Infection

Central nervous system infections antepartum or postnatally can be associated with neonatal seizures (Kairam and De Vivo, 1981). The TORCH infections (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes virus) can produce structural brain changes resulting in a predilection for seizures and encephalopathy. These infections are discussed in detail in the Infectious Disease section. Neonatal herpes encephalitis is associated with specific EEG findings, with focal or multifocal epileptiform discharges that may be periodic or quasiperiodic in nature (Mizrahi and Tharp, 1982; Mikati et al., 1990). Enteroviruses may also present with encephalopathy and seizures (Verboon-Macielek et al., 2005, 2006, 2008).

Bacterial meningitis from group B streptococci, *Escherichia coli*, *Listeria monocytogenes*, or *Mycoplasma* may also present with encephalopathy with seizures and may be complicated by abscess formation (Gaschignard et al., 2011; Chu et al., 2014). Some neonates with bacterial meningitis may suffer further complications of arterial stroke or cerebral venous sinus thrombosis, with further neurologic injury (Fitzgerald and Golomb, 2007). A prolonged course of seizures (>72 hours) or markedly abnormal EEG pattern is associated with poor outcome in this setting (Klinger et al., 2000, 2001).

More recently, the Zika virus, a flavivirus transmitted via mosquitoes, has gained attention because of an association with microcephaly in patients born to infected mothers (Schuler-Faccini et al., 2016). Neuroradiologic investigations of these affected neonates demonstrate intracranial calcifications, destructive lesions, or brain malformations including polymicrogyria and pachygyria (de Fatima Vasco Aragao et al., 2016). While reports thus far do not specify neonatal seizures as a presenting feature, one would anticipate a higher risk of this secondary to the associated structural lesions or if a meningoencephalitis remained present.

Metabolic Derangements

Electrolyte disturbances such as hypoglycemia, hypocalcemia, hypomagnesemia, or hyponatremia or hypernatremia may result in seizures; repletion of glucose or electrolytes is imperative for treatment. Further aspects of these etiologies are discussed later.

Hypoglycemia

Hypoglycemia is generally accepted as a glucose level less than 47 mg/dL, although the definition remains controversial (Heck and Erenberg, 1987; Sinclair, 1997; Committee on Fetus and Newborn and Adamkin, 2011). Infants of diabetic mothers and small for gestational age neonates are at risk for transient hypoglycemia, but hyperinsulinism or inborn errors of metabolism should be considered in neonates with persistent hypoglycemia. Hypoglycemia may coexist with hypoxic-ischemic injury or with hypocalcemia, both of which may also result in seizures. Jitteriness, tremors, and abnormal tone may be present in neonates with hypoglycemia, mimicking seizure. Persistent or profound hypoglycemia may result in cerebral injury, classically described as white matter injury or occipital injury (Griffiths and Laurence, 1974; Tam et al., 2008).

Seizures themselves should first be treated by correction of hypoglycemia; seizures may persist despite correction, particularly if cerebral injury occurs. Infants with hypoglycemia and cerebral injury may later develop occipital lobe epilepsy, although the severity of the epilepsy varies (Fong and Harvey, 2014).

Hypocalcemia

Hypocalcemia is defined as a total calcium level of less than 8.0 mg/dL in term neonates and less than 7.0 mg/dL in preterm neonates or an ionized calcium of less than 3.0 mg/dL (0.75 mmol/L) (Beers et al., 1999). Neonates with hypocalcemia may present with seizures secondary to increased excitability of the cell membrane (Nardone et al., 2016), thus resulting in exaggerated startles, jitteriness, myoclonic jerks, or seizures (Keen, 1969; Jain et al., 2010). Hypocalcemia that is not responsive to repletion may be secondary to hypomagnesemia, which should be checked and corrected as appropriate (Jain et al., 2010). Early-onset hypocalcemia may be seen in infants of diabetic mothers, small for gestational age infants, or in hypoxic-ischemic injury, as well as hyperparathyroidism (Jain et al., 2010). Late-onset presentations are often secondary to endocrine etiologies. Other neurologic considerations in late-onset presentation include 22q11 deletion syndromes, which may present with hypocalcemia, cardiac defects, and brain abnormalities; recent studies suggest that neonatal hypocalcemia and resultant seizures may increase the risk of intellectual disability in this population (Cheung et al., 2014).

Hyponatremia and Hypernatremia

Hyponatremia is a cause of seizures across the life span (Nardone et al., 2016); however, it is relatively rare in neonates. When present, this may reflect an inappropriate secretion of antidiuretic hormone in the setting of trauma, asphyxia, or infection (Volpe, 2008). Hypernatremic seizures are also rare in neonates but may be secondary to congenital adrenal disorders or iatrogenic from intravenous solutions with high sodium concentrations.

Drug Withdrawal and Intoxication

Newborns of mothers with polysubstance abuse may be at an increased risk of seizures in the neonatal period. Prenatal exposure to opiates such as methadone or heroin can result in neonatal abstinence syndrome, which, in the most severe cases, can result in seizures (Herzlinger et al., 1977). Neonates born to mothers with acute intoxication of alcohol have a predilection to seizures caused by withdrawal (Pierog et al., 1977). Cocaine, a stimulant with well-studied effects, can produce seizures in neonates either secondary to intoxication caused by maternal ingestion or from

resultant withdrawal (Kramer et al., 1990; Chiriboga et al., 1993). Cocaine may also result in neonatal stroke, which in turn increases the risk of seizures. Exposure to other stimulants, such as methamphetamine, may be associated with a withdrawal syndrome and jitteriness, tremor, and exaggerated startle, but seizures have not been classically reported (Hudak et al., 2012).

Maternal use of SSRIs such as fluoxetine, paroxetine, and sertraline may also result in a withdrawal syndrome in neonates. Clinical symptoms include tremor, jitteriness, vomiting, diarrhea, and sleep disturbance. In some cases, convulsions may be present as a component of the withdrawal syndrome (Sanz et al., 2005). EEG remains imperative in diagnosis, however, as not all abnormal movements noted may have an EEG correlate.

Inadvertent fetal injection with local anesthetic to the pudendal nerve during delivery may result in neonatal intoxication with subsequent seizures (Dodson, 1976; Hillman et al., 1979). Reported newborns presented with apnea, bradycardia, hypotonia, and encephalopathy within the first 6 to 8 hours of life. If the mother received a pudendal nerve block, the newborn's scalp and body should be assessed for potential puncture marks as site of entry. Treatment in this scenario is supportive, with diuresis, acidification of urine, and dialysis as indicated.

Congenital Brain Malformations

Brain malformations occurring from disorders or disruptions in neurodevelopment may result in seizures in the newborn period. These disorders are discussed in greater detail elsewhere but are caused by alterations in stages of induction, segmentation, proliferation, migration, synaptogenesis, and myelination. Seizures may present in the newborn period because of the physiologic stress of birth, which may lower seizure thresholds. Encephalopathy is typically present and may coexist or be mistaken for birth asphyxia. Close attention to physical examination may help in distinguishing these malformations as neonates with lissencephaly or holoprosencephaly have distinct facial features. Neuroimaging with magnetic resonance techniques will verify these abnormalities. Many brain dysgenesis disorders lack specific physical examination findings, and thus neuroimaging is recommended for all neonates with seizures. One study demonstrated that 9% of 356 neonates with seizures were found to have brain malformations (Sheth et al., 1999).

Neonates with brain dysgenesis and seizures in the neonatal period have the greatest likelihood of developing epilepsy among all causes of neonatal seizures (Watanabe et al., 1982).

Inborn Errors of Metabolism

Biochemical abnormalities are rare causes of neonatal seizures, accounting for between 1% and 4% of cases (Volpe, 2008; Vasudevan and Levene, 2013). Although rare, consideration of this etiology is imperative, as specific treatments may be available for some causes, based on the enzymatic defect uncovered. In cases where treatment is not available, prognostic implications remain essential.

Pregnancy and delivery history may be unremarkable; however, the newborn may have encephalopathy, hypotonia, poor feeding, and seizures in the first few days of life to harken the necessity of additional investigation. Other newborns, however, may have difficulty during delivery, thus a high level of clinical suspicion is necessary in neonates with refractory seizures. Signs suggestive of an inborn error of metabolism include seizures that start prenatally,

refractory seizures requiring multiple AEDs, progressive clinical worsening, or deterioration of EEGs (Ficicioglu and Bearden, 2011). Specific neuroimaging may demonstrate characteristic lesions supporting a metabolic etiology. These are nicely reviewed elsewhere (Poretti et al., 2013).

Inborn errors of metabolism causing seizures may be placed in three categories: defects in neurotransmission; disorders of energy production; and disorders associated with a brain malformation, destruction, or dysfunction on a metabolic basis (Van Hove and Lohr, 2011). Examples of each are given below, although extensive review of inborn errors is beyond the scope of this chapter.

Defects in neurotransmission include glycine encephalopathy and pyridoxine-dependent epilepsy. Glycine encephalopathy, also known as nonketotic hyperglycinemia, is due to deficiencies in the ability to cleave glycine. Glycine has both inhibitory and excitatory neurotransmitter activities, and glycine encephalopathy presents with apnea, myoclonic seizures, and burst suppression on EEG. In retrospect, mothers will often note that significant hiccups were present in utero, representing myoclonic seizures. Seizures may initially respond to benzodiazepines, but, long term, patients develop early myoclonic encephalopathy, or Ohtahara syndrome (Van Hove et al., 2002).

Pyridoxine-dependent epilepsy is an uncommon but treatable cause of neonatal seizures, caused by deficiency of antiquitin, an enzyme involved in the lysine catabolic pathway. Newborns may present with seizures, encephalopathy, and hypotonia in the first few days of life (Gospe, 2001 [updated 2014]). In retrospect, mothers may report paroxysmal in utero movements representing seizures. In some patients with pyridoxine-dependent epilepsy, lactic acidosis and other biochemical abnormalities may be present, mimicking features of neonatal encephalopathy secondary to hypoxia or ischemia. Therefore a diagnosis of pyridoxine-dependent epilepsy should be considered in newborns with presumed hypoxic-ischemic encephalopathy and seizures refractory to AEDs. Seizure types and EEG findings may vary between patients, with a predilection toward status epilepticus. It is an autosomal recessive condition, caused by a genetic mutation in *ALDH7A1*, and affected patients have elevated levels of α -amino adipic semialdehyde (AASA) in blood and urine (Stockler et al., 2011). Historically, injection of intravenous pyridoxine in patients with status epilepticus was recommended as it may result in significant improvement of EEG; however, it is now suggested that enteral pyridoxine be administered until biochemical or genetic testing excludes the diagnosis, as immediate intravenous response varies (Bok et al., 2010). Pyridoxine 30 mg/kg divided three times daily is suggested.

Examples of disorders of energy production and utilization include urea cycle defects and glucose transporter type 1 (GLUT1) deficiency. Urea cycle defects may present with encephalopathy and seizures in the first 2 days of life with significant hyperammonemia. Seizures occur as toxic breakdown products accumulate. Testing of serum ammonia and glucose levels, urine organic acids, plasma amino acids, and acylcarnitine levels may reveal the diagnosis. Treatment includes dialysis or exchange transfusion while determining the enzymatic defect, alongside dietary adjustments such as the limitation of protein.

Glucose transport to the brain is mediated by GLUT1. Reduced glucose transport through the blood-brain barrier results in hypoglycorachia (cerebrospinal fluid [CSF] glucose levels <45 mg/dL or a ratio of CSF to serum glucose of <0.4). Patients may present in the first few months of life with significant seizures. Low CSF glucose without alternate explanation should prompt further genetic testing of *SLC2A1*, the major genetic defect found

in this disorder (Wang and de Vivo, 2002). Over the past decade, the phenotype of patients has expanded significantly to include those with movement disorders or early-onset absence epilepsy (Leen et al., 2010). Treatment of GLUT1 deficiency is the ketogenic diet, thereby limiting the necessity of transporting glucose to support brain metabolism.

Metabolic disorders resulting in brain dysgenesis include peroxisomal biogenesis disorders such as Zellweger syndrome. Infants present with characteristic facial features, hypotonia, and encephalopathy alongside seizures in the first days to weeks of life. Neuroimaging reveals neuronal migration defects such as polymicrogyria, while very long chain fatty acids are elevated. Mutations in the *PEX* gene family have been associated with this group of metabolic disorders (Braverman et al., 2016).

Progressive Neonatal Epilepsy Syndromes

Seizures in the neonatal period are rarely the presentation of a chronic epileptic condition (Mizrahi and Clancy, 2000). Affected neonates may endure myoclonic seizures, with early myoclonic encephalopathy, or have frequent or multifocal seizures. Rarely, migratory seizures may be present. When seizures appear progressive, evaluation for underlying etiology should occur. These neonatal syndromes may be termed *early infantile epileptic encephalopathy*, or *Ohtahara syndrome*, and the EEG may demonstrate a suppression-burst pattern or disorganized background. This syndrome typically presents with seizures in the first few weeks to months of life. Some neonates may have demonstrable brain malformations or metabolic disease. Over the past decade, many genes have been associated with early-onset epileptic encephalopathies, including mutations in *ARX*, *CDKL5*, and *STXBPI* among others. These are reviewed elsewhere (Nieh and Sherr, 2014; Gursoy and Ercal, 2016).

Benign Familial Neonatal Seizures

A rare form of neonatal epilepsy that is inherited in an autosomal dominant pattern should be considered in newborns with a positive family history (Pettit and Fenichel, 1980) or after structural, infectious, metabolic, and toxic causes have been ruled out. Often the parents are unaware that they had a seizure in the newborn period until grandparents note this after their grandchild presents with neonatal seizures. Several genes have been implicated, including two potassium channel genes, *KCNQ2* and *KCNQ3*, as well as a sodium channel gene *SCN2A* (Berkovic et al., 2004; Heron et al., 2007; Grinton et al., 2015). *KCNQ2* mutations may also result in a progressive epileptic encephalopathy; thus caution should be exercised in counseling regarding prognosis (Allen et al., 2014). Infants with benign familial seizures typically have a normal interictal pattern on EEG and normal neuroimaging, while those who develop an epileptic encephalopathy tend to have abnormal EEGs with burst suppression, multifocal epileptiform discharges, and basal ganglia hyperintensities (Weckhuysen et al., 2012). Infants with benign neonatal epilepsies tend to have a good response to AEDs, with reports of sodium channel agents being effective in those with *KCNQ2* mutations (Pisano et al., 2015).

Treatment of Seizures

Once the diagnosis of neonatal seizures has been made, management is initiated while the determination of an etiology is under way. Initial efforts should be geared toward detecting correctable causes

of neonatal seizures, such as hypoglycemia, hypocalcemia, or sodium disturbances. Hypoglycemia may be corrected with infusion of 10% dextrose at 2 mL/kg and, depending on the duration of hypoglycemia, may require dextrose infusions to maintain euglycemia. Seizures caused by hypocalcemia should be treated with 10% calcium gluconate in early-onset cases and oral calcitriol or calcium in late-onset cases (Beers et al., 1999). Magnesium levels should be checked and repeated if necessary, as hypomagnesemia may coexist with hypocalcemia. Although rare causes of seizures, hyponatremia or hypernatremia can be managed with determination of the underlying etiology and fluid restriction or replacement dependent on the etiology of sodium dysregulation.

As discussed earlier, pyridoxine-dependent epilepsy is an important etiologic consideration in the newborn presenting with seizures. It is recommended that neonates undergo evaluation for pyridoxine-dependent epilepsy either by testing for the presence of AASA in urine or plasma, measurement of CSF neurotransmitter metabolites (which will show characteristic patterns on chromatography), or testing for mutations in the *ALDH7A1* gene. These laboratory studies should be pursued while the baby is being treated empirically with enteral vitamin B₆ (Bok et al., 2010).

Antiepileptic Drugs

Once metabolic derangements are addressed, treatment of seizures is undertaken with AEDs. As neonates may have both clinical and electrographic seizures, and treatment with AEDs may result in electroclinical dissociation, it is recommended that neonates undergoing treatment with AEDs be monitored through continuous EEG (Shellhaas et al., 2011).

Phenobarbital has remained the first-line choice for treatment of neonatal seizures by most clinicians (Bartha et al., 2007; Blume et al., 2009). Phenobarbital is a barbiturate, acting on the γ -aminobutyric acid (GABA) receptor, enhancing GABA activity. Phenobarbital is typically given as an intravenous bolus of 20 mg/kg, with a maintenance dose of 4 mg/kg per day. The half-life of phenobarbital is quite long in the neonate, approximately 45 to 200 hours (Lockman et al., 1979). Therapeutic levels should be assessed as levels above 40 μ g/mL may not have additional therapeutic benefit (Gilman et al., 1989).

Treatment choices beyond phenobarbital vary greatly between providers (Bartha et al., 2007; Blume et al., 2009). The best evidence for use currently is for phenytoin or fosphenytoin (Painter et al., 1999). Phenytoin should be administered at a dose of 15–20 mg/kg; a water-soluble form that is better tolerated is fosphenytoin, which may be given at the same dose of phenytoin equivalents (Painter et al., 1978). Phenytoin levels are often difficult to maintain, as the medication is rapidly redistributed to the tissues and follows zero-order kinetics (Painter et al., 1981).

Benzodiazepines, such as midazolam, diazepam, or lorazepam, may also be used to control refractory neonatal seizures. Intravenous midazolam has been studied in neonates for safety and efficacy and may be an option for neonates with refractory seizures (Sheth et al., 1996; Castro Conde et al., 2005). Lidocaine, a sodium channel antagonist, has equal efficacy as compared with midazolam for refractory seizures (Shany et al., 2007; Lundqvist et al., 2013; Weeke et al., 2016). This medication is used more commonly in Europe than in the North American continent (Bartha et al., 2007; Vento et al., 2010).

Because of the limited efficacy of AEDs, newer medications are often used off-label by neurologists (Silverstein and Ferriero, 2008). Levetiracetam has been reported in case series to be efficacious, as

has topiramate (Furwentsches et al., 2010; Abend et al., 2011; Glass et al., 2011a). Currently, randomized control trials are under way on a larger scale to assess the safety and efficacy of these agents (Pressler and Mangum, 2013). Bumetanide, a loop diuretic, is a neuronal NKCC (sodium–potassium chloride cotransporter) antagonist and has been shown in preclinical studies to be effective in treating neonatal seizures (Dzhala et al., 2005). The NKCC receptor is expressed in immature neurons, and its activation results in elevated intracellular chloride levels; bumetanide reverses this chloride gradient. A recent open-label feasibility trial to assess its effects in neonates with seizures caused by hypoxic–ischemic encephalopathy did not find an improvement of seizures with bumetanide after treatment with phenobarbital and may have found increased rates of hearing loss (Pressler et al., 2015). Further trials are under way to study bumetanide in this population.

Efficacy of Antiepileptic Drugs

Finding new AEDs for treatment of neonatal seizures is imperative given available data regarding the efficacy of currently used AEDs. Although exact rates vary, studies show a complete response to phenobarbital in less than 50% of neonates (Painter et al., 1978, 1999; Lockman et al., 1979). Clinical studies have varied with regards to endpoint, assessing the cessation of clinical rather than electrographic seizures; however, electrographic seizures may continue despite cessation of clinical seizures (Weiner et al., 1991). As phenobarbital works at the GABA receptor, understanding GABA in the immature brain is imperative in finding appropriate methods in the treatment of seizures. Intracellular chloride concentration determines the strength of GABAergic transmission; in neonates, there are high levels of intracellular chloride, secondary to the developmental expression of the NKCC receptor in these immature neurons (Dzhala et al., 2005; Kahle and Staley, 2008). This developmental expression of NKCC and resultant depolarization of the GABA receptor may be important for calcium-dependent processes such as neuronal migration and synaptogenesis (Brooks-Kayal, 2005). In animal studies, this appears to contribute to the poor efficacy of phenobarbital, such that the addition of bumetanide, an NKCC antagonist, increases the efficacy of phenobarbital in treating seizures (Dzhala et al., 2008).

Discontinuation of Antiepileptic Drugs

How long to treat a neonate with AEDs after resolution of seizures remains an area of uncertainty and controversy (Guillet and Kwon, 2008). It is recognized that the commonly used AEDs complicate assessments of arousal, tone, and feeding abilities because of their sedating qualities. It is now generally recommended that, when possible, AEDs be discontinued in the neonatal intensive care unit (NICU), given the low rate of seizure recurrence after early AED withdrawal. Retrospective studies have demonstrated that there is a low rate of seizure recurrence after early discontinuation of AEDs and that longer length of treatment did not prevent later development of epilepsy (Hellstrom-Westas et al., 1995; Guillet and Kwon, 2007). There is the additional concern of the effects of AEDs on the immature brain. Animal studies show increases in apoptosis after treatment with phenobarbital and phenytoin amongst other AEDs (Mizrahi, 1999; Bittigau et al., 2003).

Additionally, most children with neonatal seizures do not have seizure recurrence in the first year of life (Pisani et al., 2015), and thus AEDs need not be continued. Seizures in infancy that present with specific epilepsy syndromes, such as infantile spasms, require

specific treatments and do not typically respond to the AEDs used in the newborn period. However, neonates with congenital brain malformation or progressive epilepsy syndromes have an ongoing risk for seizures and thus would be expected to continue on AEDs.

Prognosis

A question typically faced by the clinician in the NICU is the prediction of how a newborn will fair in the near and distant future. Immediate concerns in the NICU often include respiratory compromise, either secondary to the underlying etiology or caused by the sedative effects of AEDs. The first neurodevelopmental milestone the newborn often faces is successful feeding, with many neonates requiring extra time or enteral tube support in the NICU. Beyond this newborn period, prognostic considerations remain, particularly with long-term neurodevelopment and epilepsy.

The etiology of a newborn's seizure largely accounts for the overall outcome. Prediction of neurodevelopmental outcomes relies first and foremost on the cause of seizures and is often dependent on advanced neuroimaging that may elucidate congenital malformations or areas of brain injury. Newborns who escape motor impairments in early childhood may still develop more subtle neuropsychological challenges as adolescents or early adults (Temple et al., 1995).

Neurophysiologic data also play a role in prognostication (Monod et al., 1972; Sharp et al., 1981; Sinclair et al., 1999). Those infants with a persistently abnormal EEG pattern such as burst suppression are likely to have a poor outcome, especially when this persists on serial EEGs (Sinclair et al., 1999). Neonates with a normal EEG tend to fair better, while those with moderately abnormal EEGs have a variable outcome (Sharp et al., 1981).

Seizures themselves play an uncertain role in neurodevelopmental outcomes and remain a controversial area in neonatal neurology. Animal models show less vulnerability to seizure-induced brain injury in the neonatal brain as compared with the adult brain (Huang et al., 1999). Despite reduced cell death, it has been shown that seizures in the immature brain result in changes in neural circuitry not seen in the mature brain. In the neonatal rat hippocampus exposed to anoxia, stimulation of electrographic seizures resulted in anoxic depolarization and neuronal death twofold greater than when no seizures were present (Dzhala et al., 2000). Other studies have shown that recurrent seizures in neonatal rats result in spine loss of pyramidal cells in the hippocampus and also affect neurogenesis by altering expression of glutamate and GABA receptors (Holmes, 2009). The effect of recurrent seizures in the neonatal rat results in reduced cell number, despite less cell death (McCabe et al., 2001). These changes in the hippocampus may later result in epilepsy (Holmes, 2009).

There are ethical concerns in studying the effects of neonatal seizures rigorously in the human newborn, and thus limited studies are available. Structural studies have shown that seizure severity is independently associated with brain injury, as measured by magnetic resonance spectroscopy (Miller et al., 2002). Studies assessing the independent role of clinical seizures in the neonate with hypoxic–ischemic encephalopathy have shown mixed results. One study demonstrated lower full-scale intelligence quotient at 4 years of age when correcting for severity of brain injury on MRI (Glass et al., 2009b), while another found no difference on 18-month outcomes on the Bayley Scales of Infant Development (Kwon et al., 2011). The independent role of electrographic seizures remains uncertain. Neonates with status epilepticus confirmed on EEG

have worse neurodevelopmental outcomes and often develop postnatal epilepsy (Pisani et al., 2007). McBride et al. (2000) reported on 40 neonates with electrographic seizures compared with 28 neonates without electrographic seizures, where electrographic seizures were associated with microcephaly, cerebral palsy, and failure to thrive. A recent randomized controlled trial prospectively studied neonates with electroclinical and electrographic seizures, treating one group for electroclinical seizures only, while treating all electrographic seizures (including those without a clinical correlate) in the other group. This study found that newborns in whom all electrographic seizures were treated had a lower seizure burden and received treatment earlier. Additionally, although underpowered, this study suggested that greater seizure burden was associated with greater injury and lower Bayley Scores of Infant Development (Srinivasakumar et al., 2015).

Postnatal Epilepsy

Newborns with seizures acutely in the neonatal period remain at risk for developing epilepsy, defined as recurrent unprovoked seizures, in later life. It is estimated that nearly a quarter of neonates with seizures symptomatic of an underlying cause go on to develop postnatal epilepsy (Clancy and Legido, 1991; Pisani et al., 2004, 2012; Glass et al., 2011). Individual reports vary, but a recent review of published studies found that nearly 20% of newborns with seizures go on to develop postnatal epilepsy, with two-thirds presenting with recurrent seizures in the first year of life (Pisani et al., 2015). Typically, there is a latency period between neonatal seizures and onset of postnatal epilepsy. Neonates with refractory seizures, requiring multiple AEDs, severe brain injury, or those with persistent interictal epileptiform discharges on EEG have a higher risk of developing postnatal epilepsy (Rose and Lombroso, 1970; Watanabe et al., 1982; Clancy and Legido, 1991).

Conclusions

Seizures are a relatively frequent occurrence in the NICU. A high level of suspicion is necessary, alongside ancillary testing to

distinguish seizure from its mimickers. Once diagnosed, management should be geared toward determination of etiology, as well as treatment of seizures. Although it is accepted that status epilepticus should be avoided, the independent impact of neonatal seizures on neurodevelopment remains controversial. There is a growing body of preclinical and clinical data suggesting that electrographic seizures impact later outcomes of neurodevelopment and epilepsy. Our first-line AEDs, however, are inadequate in treating seizures, and further research is under way to find more effective medications.

Risk Assessment and Neurodevelopmental Outcomes

SARA B. DEMAURO AND SUSAN R. HINTZ

KEY POINTS

- Preterm and critically ill infants are at high risk for cognitive and motor development problems, neurobehavioral and executive function problems, learning and academic problems, neurosensory problems, and poor functional outcomes.
- Neonatal morbidities, socioeconomic factors, and early interventions can influence long-term outcomes for high-risk infants.
- Many adverse school-age, adolescent, and adult outcomes of high-risk infants cannot be easily predicted in early childhood. Assessments into school age, adolescence, and adulthood are critically important to understand the lifetime trajectory of former high-risk infants.
- Cognitive and neurobehavioral challenges among high-risk children are associated with increased resource utilization and costs.
- All high-risk infants and their families must have access to comprehensive, multidisciplinary developmental follow-up programs and early intervention services in order to optimize both short-term and long-term outcomes.

Outcome Assessment in High-Risk Infants

Who Is the “High-Risk” Infant?

The term *high-risk infant* has been defined in many ways and has been burdened with many negative connotations. However, one general goal for attempting to delineate infants who are high risk is to heighten awareness and focus on those children who may benefit from increased surveillance and early intervention across a number of domains. In a policy statement from the American Academy of Pediatrics (AAP) (AAP, 2008), high-risk infants were defined broadly as including (1) the preterm infant; (2) the infant with special healthcare needs or dependence on technology; (3) the infant at risk because of family issues; and (4) the infant with anticipated early death. Others have underscored the importance of critically assessing risk in any infant admitted to the neonatal intensive care unit (NICU) or special care nursery (Walker et al., 2012). Many clinical conditions and risk factors seen in term-born infants, including but not limited to congenital heart disease (CHD) (Marino et al., 2012), need extracorporeal membrane oxygenation (ECMO) in the neonatal period (Ijsselstijn and Van Heijst, 2014),

and hypoxic-ischemic encephalopathy (HIE) regardless of treatment with therapeutic hypothermia (Shankaran et al., 2005, 2012a) places them at high risk for neurologic, developmental, functional, and health outcome challenges in early childhood and beyond. Unfortunately, although the risks for postdischarge difficulties, in addition to medical morbidities, have been increasingly well-described in the literature for these and other predisposing risk factors, the neurodevelopmental needs of many of these term-born, high-risk infants may be overlooked at hospital discharge, or they may not be appropriately referred to early intervention services even when they are identified as eligible in follow-up (Tang et al., 2012).

Preterm infants are the most recognized and targeted population of high-risk infants. Preterm birth, defined by the World Health Organization (WHO) as delivery before 37 completed weeks of pregnancy, is a growing problem for developing countries across the world (Blencowe et al., 2012). Preterm birth remains a substantial problem for developed nations as well, although the landscape of prematurity appears to be changing. According to the Centers for Disease Control and Prevention National Center for Health Statistics, in the United States, in 2013, the preterm birth rate (proportion of live births <37 weeks' estimated gestational age, [EGA]) was 11.39%, which was very slightly decreased from the 2012 preterm birth rate of 11.55% (Martin et al., 2015). Nevertheless, this represents a considerable decline from the preterm birth rate peak of 12.8% in 2006. Furthermore, rates of preterm birth declined for each of the largest race and Hispanic origin groups and for 49 of the 50 United States over that period. However, the proportion of infants delivered very preterm (VPT, <32 weeks' EGA) stands at 1.92%, which, although decreased from 2.04% in 2006 and 2007, remains relatively unchanged. Similarly, the extremely preterm (EPT, <28 weeks' estimated EGA) birth rate is relatively stable; in 2013 the EPT birth rate was 0.73%, exactly the same as 2012 and 2011, and minimally changed from a peak of 0.77% in 2005. Although a decrease in overall preterm birth rate has been realized, and the VPT and EPT birth rates seem to be miniscule, the impact in terms of total births is important. With nearly 4 million births annually in the United States, approximately 450,000 neonates <37 weeks' EGA, 75,000 very preterm neonates, and 30,000 EPT neonates were born in 2013 alone (March of Dimes Peristats, 2016).

What Is Meant by “Outcomes”?

As survival of even the most EPT and complex infants has improved over the decades, short-term mortality and morbidities have moved from being the only outcomes reported for high-risk infants to being only the first of many outcomes of interest. There is increasing recognition of the critical significance of understanding later outcomes in order to evaluate the true impact of interventions and management approaches in the NICU, to inform counseling, and direct early detection and preventive care. Certainly, for some trials of treatments and management strategies designed to test a hypothesis of improved in-hospital morbidities, the primary outcome may best be short term (Schmidt et al., 2006; SUPPORT Study Group of the Eunice Kennedy Shriver NICHD Neonatal Research Network et al., 2010; BOOST II United Kingdom, Australia and New Zealand Collaborative Groups et al., 2013). However, longer-term follow-up or later primary endpoints may provide valuable additional outcomes data, safety assessments, or information about functional elements (Schmidt et al., 2001, 2012, 2013; Vaucher et al., 2012; BOOST-II Australia and United Kingdom Collaborative Groups et al., 2016).

What are these postdischarge outcomes of potential importance? How are they measured, and what are the barriers or benefits of focusing on various outcomes? The value placed on one outcome or group of outcomes may differ greatly for families, children, and adults who were born high risk, physicians, and other care providers, investigators, educators, and those involved in developing public policy. The importance of various outcomes may also vary substantially among individuals within these groups and across different time points of their lives. Furthermore, later cognitive and behavioral outcomes are complex and influenced by the postdischarge environment, relationships, and biologic factors (Msall and Park, 2008; Treyvaud et al., 2012). Therefore the concept that there is one “best” outcome measure among those born preterm or at high risk is ill conceived.

In the following section, we provide an overview of some general later outcome categories that have been reported and proposed for high-risk infants, particularly for those born preterm or with very low birth weight (VLBW). We begin with special attention to early neurodevelopmental outcomes assessments (18 to 36 months) since these are most frequently reported in trials and prospective observational studies. We discuss challenges and strengths reported at this age, using frequently reported definitions of impairment and disability, and describe the usual battery of tests and assessments. Limitations of standard outcomes definitions and challenges to interpretation of early neurodevelopmental outcome studies are considered. We also highlight abilities and difficulties assessed through school age and adulthood.

Early Neurodevelopmental Outcome Assessments

For the vast majority of interventional trials and prospective observational studies involving high-risk infants, neurodevelopmental outcome at approximately 2 years corrected age, and usually death or “neurodevelopmental impairment” (NDI), is reported as a primary outcome. Although the rationale for the combined outcome is clear in the setting of competing outcomes, there is ongoing and substantial debate regarding the appropriateness of this outcome as a gold standard for all trials (Marlow, 2013, 2014). Furthermore, the NDI outcome is itself a composite outcome, composed of morbidities from neurodevelopmental and sensory domains with

different risk profiles, causal pathways, and predictive validity. There are challenges to interpretation of these data, potential limitations in terms of comparisons across cohorts and across years, and concerns regarding the value of early neurodevelopmental outcomes to predict abilities and challenges in later childhood and beyond.

During a follow-up visit at 2 to 3 years, the traditional battery of tests and assessments includes assessment of motor function, cognitive/developmental capabilities, and neurosensory outcomes including hearing and vision impairments. These general components have been proposed and recommended by expert panels and working groups, including the British Association of Perinatal Medicine (Wang et al., 2006; British Association of Perinatal Medicine, 2008), and within the context of prospective studies and trials (Schmidt et al., 2001; Doyle, 2010a; Moore et al., 2012; Vohr et al., 2012) although the specific evaluations within each area differ among groups and over time. (See later section *Multi-disciplinary Follow-up Care for the High-Risk Infant* for further details.)

Motor Function

Motor impairments including cerebral palsy (CP) are among the most frequently reported neurodevelopmental outcomes for high-risk infants. Motor difficulties may become evident over months or years, yet timely identification of motor difficulties may allow for interventions to improve outcomes, thereby reinforcing the critical importance of vigilant long-term follow-up (see later section *Challenges to and Importance of Follow-Up*). CP is defined as a disorder of movement and posture that involves abnormalities in tone, reflexes, coordination and movement, delays in motor milestone achievement, and aberration in primitive reflexes that is permanent but not unchanging and is caused by a nonprogressive interference, lesion, or abnormality of the developing immature brain (Bax et al., 2005; Fawke, 2007). CP is also categorized by type (spastic, dyskinetic, or dystonic); topography (limbs involvement); and descriptors of extent and pattern of involvement (monoplegia, diplegia, hemiplegia, and quadriplegia). CP sometimes cannot be diagnosed with confidence until after 18 months, although earlier examinations of general movements and other factors may elevate risk profile for CP and can serve to focus and underscore the need for follow-up (Spittle et al., 2011, 2013a).

The Gross Motor Function Classification System (GMFCS) (Palisano et al., 1997, 2007; Rethlefsen et al., 2010) provides a valid and reliable system to classify the extent of activity limitation in CP. It is a five-level system (I–V) used to categorize children up to 18 years of age based on their usual performance, with a focus on functional capabilities, including sitting, mobilizing, walking, and need for assistive devices. Such classification helps clinicians communicate information about severity, choice of interventions, and prognosis in a standardized, easy-to-use, valid, and reliable way.

Higher level on the GMFCS is associated with increasing functional difficulty, but, of note, distinctions between levels I and II are not as significant as differences between other levels, particularly for younger children. Children classified as level I overall are able to walk without restrictions but may have difficulty with the speed, balance, and coordination required for higher-level skills; between 2 and 4 years, they are able to floor sit with both hands free to manipulate objects, move in and out of floor sitting and standing without adult assistance, and they walk as the preferred method of mobility without the need for any assistive mobility device. In contrast, children classified as level V are profoundly

impaired with no means for independent mobility; between 2 and 4 years, this is described as physical impairments that restrict voluntary control of movement and the ability to maintain antigravity head and trunk postures and functional limitations in sitting and standing that are not fully compensated with the use of adaptive equipment.

GMFCS categorization in children less than 2 years old depends predominantly on the amount of support required for the child to sit and also considers more advanced skills such as crawling and walking. Although some children diagnosed before 2 years of age will require reclassification, most are not reclassified by more than one level. The positive predictive value (PPV) of a classification of GMFCS level I, II, or III (child will walk with or without aids) as compared with level IV or V (child will probably need a wheelchair for mobility) is very high (0.96). Thus the GMFCS provides a sound approximation, rather than a definitive final categorization, in this age group (Gorter et al., 2009).

Although CP with severe functional limitations is of great concern, it is relatively rare. An Australian CP registry review from the 1970s to 2004 showed increasing prevalence of CP in the 1970s and 1980s attributed to the increasing survival of EPT infants; however, CP rates stabilized or decreased between the early 1990s and 2004 (Reid et al., 2011; Spittle and Orton, 2014). In children with CP, there may be a spectrum of motor findings, including many motor and coordination deficits that should not be overlooked (Vohr et al., 2005).

There are numerous motor and coordination challenges apart from CP that are reported in high-risk children, including those born preterm. Developmental coordination disorder (DCD) is a diagnosis that is considered best made at or after 5 years, but motor performance assessment tools are available from 3 years. DCD is diagnosed when (1) motor coordination and performance are below that expected for the child's chronologic age and intelligence level, (2) the motor disorder interferes with activities of daily living or academic achievement, (3) it is not due to a general medical or neurologic condition such as CP, and (4) the motor difficulties are in excess of those associated with any intellectual disability that is present. (Sugden et al., 2006; Blank et al., 2012). Current recommendations for diagnosis of DCD include a score less than the 15th percentile on the Movement Assessment Battery for Children (Henderson et al., 2007) or equivalent test such as the Bruininks–Oseretsky Test of Motor Proficiency (Bruininks and Bruininks, 2005), whereas previous guidelines recommended using a score less than the fifth percentile on the Movement Assessment Battery for Children. However, a movement or motor test alone is not sufficient for the diagnosis of DCD, as direct observation or interviews are essential to determine the extent of interference with activities of daily living. It is important to remember that although the motor difficulties associated with DCD are usually considered “minor” motor impairments, particularly in comparison with disabling CP, nonetheless they can have significant impact on the child. These difficulties may include important functional skills such as fine motor skills, speed and accuracy in motor planning, balance, and coordination. Children with DCD or probable DCD have been shown to be at increased risk for reading and attention difficulties, social–emotional and behavior problems, anxiety, speech and language impairment, and other challenges (Kirby and Sugden, 2007; Lingam et al., 2012).

Cognitive Assessment

A central component of a high-risk infant neurodevelopmental follow-up visit has been administration of a standardized

developmental test. These tests are intended to provide a measure of “cognitive” function, although there are widely acknowledged limitations including the evolution of test versions making it difficult to compare across cohorts, preclusion of extrapolation of 2- to 3-year results to intelligent quotient (IQ) at later time points, and challenges to interpretation of results in the preterm population using standardized “cut points” alone and in the absence of a contemporaneous normal birthweight (NBW) term control group (see later section [Limitations and Challenges to Interpreting Early Neurodevelopmental Outcomes Studies](#)).

The Bayley Scales of Infant and Toddler Development (BSID), with a test age range of 1 to 42 months, is now the most widely used developmental test for high-risk infants across the United States and Europe. The original version, released in 1969, was revised in 1993 (Bayley, 1993). The BSID-II had two developmental scores: the Mental Developmental Index (MDI), a composite of cognitive and language tasks, and the Psychomotor Developmental Index (PDI), a composite of fine and gross motor skills. This perceived drawback, as well as the usual drive to revise editions due to the “Flynn effect” (Flynn, 1999), contributed to the development of BSID-III (Bayley, 2006), which contains three main domains, (1) a cognitive composite score, (2) a language composite score (with receptive and expressive subscores), and (3) a motor composite score (with gross and fine motor subscores), in addition to social–emotional and adaptive behavior domains. The goal of the BSID-III was to allow identification of delays, as well as relative strengths and challenges, in specific developmental domains, and to target interventions to areas of need. However, in part because of a change in approach to norming the BSID-III, and also possibly because of separation of the cognitive and language scales, cognitive scores on the BSID-III are substantially higher than anticipated among both preterm high-risk children and term control groups (Anderson et al., 2010; Vohr et al., 2012). These findings have led to concern that the BSID-III underestimates developmental delay if utilizing normative test means alone, which has serious implications for both clinical and research endeavors. Previously, commonly used “cut points” for categorization of “moderate” and “severe” developmental delay or disability were 2 to 3 standard deviations (SD) and greater than 3 SD below the normative mean, respectively; thus for BSID-II, MDI 55 to 70 was considered a moderate delay whereas an MDI less than 55 was considered a severe delay (British Association of Perinatal Medicine, 2008; Vohr et al., 2012). However, in the absence of contemporaneous term control groups, commonly used cut points have shifted in the era of the BSID-III. Some have recommended that BSID-III cognitive and language scores less than 85 or “combined BSID-III” scores less than 80 provide the best definition of “moderate-to-severe” delay for equivalence with BSID-II MDI less than 70 (Johnson et al., 2014), whereas others have modified the threshold for cognitive delay categorization to define moderate delay as 70 to 84, severe delay 55 to 69, and profound delay as less than 54 (Schmidt et al., 2013; Vohr, 2014a).

Another developmental test, the Griffiths Scales, is available in versions for 0–2 years and 2–8 years. The first version was published in 1967, an updated version was available in 1996, and an extended and revised edition (GMDS-ER) was published in 2006. The Griffiths-III was released in 2016 (<http://www.aricd.ac.uk/about-the-griffiths-scales/>).

There are numerous cognitive development tests available to provide full-scale IQ or equivalent that have been used for later childhood assessments, including the Wechsler Preschool and Primary Scale of Intelligence (age range: 2 years 6 months to 7 years 7 months), now in the fourth edition (WPPSI-IV; Wechsler,

2012), the Differential Ability Scales (age range: 2 years 6 months to 17 years 11 months), now in the second edition (DAS-II; [Elliot, 2007](#)), and the Wechsler Intelligence Scale for Children (age range: 6 years 0 months to 16 years 11 months), now in the fifth edition (WISC-V; [Wechsler et al., 2014](#)). The Wechsler Individual Achievement Test (age range: 4 years 0 months to 50 years 11 months), now in the third edition (WIAT-III; [Wechsler, 2009](#)), identifies academic strengths and weaknesses, and has been used in clinical, research, and educational settings.

Hearing and Vision Outcomes

Severe neurosensory impairments, including profound hearing and vision impairment, among preterm infants are now low in incidence but have important long-term consequences. Rates of blindness and significant hearing impairment are inversely related to gestational age ([Hintz et al., 2011](#); [Moore et al., 2012a](#)). Both moderate-to-severe vision and hearing impairment are more common among high-risk infants and with cooccurring characteristics including male gender, multiple birth, CP, hydrocephalus, and seizures ([Davis et al., 2010](#); [Hintz et al., 2006](#); [Synnes et al., 2012](#); [Vohr 2014b](#)).

Early detection of hearing impairment is vital for optimizing speech and language development, and guidelines and recommendations reflect the importance of recognizing potential problems as early as possible. As stated in the AAP Joint Committee on Infant Hearing position statement ([AAP, 2007](#)), infants admitted to the NICU for more than 5 days are to have auditory brainstem response included as part of their predischarge screening so that neural hearing loss will not be missed; for those who fail, referral should be made directly to an audiologist for rescreening and, when indicated, comprehensive evaluation for hearing loss. Reevaluation should occur, regardless of initial evaluation results, based on individual risk factors and readmissions. All infants, including well infants, should have a hearing screening by 1 month of age, with rescreening and referral for audiology evaluation by 3 months of age for those who do not pass the initial screen. In addition, a validated global screening tool is administered to all infants at 9, 18, and 24 to 30 months or sooner when there is concern about hearing or language.

Prematurely born children have an increased risk of various ophthalmic and visual dysfunctions and abnormalities, in particular those children with a history of severe or treatment-requiring retinopathy of prematurity (ROP) and those with severe brain injury. These functional visual challenges include strabismus, problems with acuity, convergence and visual fields, and retinal morphology ([Holmström and Larsson, 2013](#)). It is important to recognize that a short-term outcome of severe ROP in the NICU may not result in the most severe functional vision outcomes in early childhood ([SUPPORT Study Group of the Eunice Kennedy Shriver NICHD Neonatal Research Network et al., 2010](#); [Vaucher et al., 2012](#)). Even children born preterm without a history of ROP or with only mild ROP also have an increased risk of problems. Long-term follow-up studies have demonstrated that up to 50% of VLBW infants have some visual impairments at later school age and that these problems can be associated with learning and academic challenges ([Stephenson et al., 2007](#)). Recommendations from AAP and the American Association of Pediatric Ophthalmology indicate that ophthalmologic follow-up should be undertaken in children with a history of ROP within 4 to 6 months after discharge, regardless of the severity of ROP ([Fierston et al., 2013](#)).

For early neurodevelopmental outcomes studies among preterm infants at 18 to 30 months corrected age, criteria for “profound” or “severe” disability in the hearing domain have generally included

some definition of “no useful hearing” even with aids or “some hearing but loss not corrected by aids,” whether accompanied by specific decibel hearing loss (dBHL) audiologic evaluation cut points (profound >90 dBHL; severe 70–90 dBHL) ([British Association of Perinatal Medicine, 2008](#)) or by examination and observation of bilateral hearing loss not correctable by amplification ([Doyle, 2010b](#); [Vohr et al., 2012](#); [Serenius et al., 2013](#)). Similarly, “severe” disability in the visual domain has generally been defined as functional bilateral blindness, including visual acuity less than 20/200, or inability to perceive light, or only able to perceive light or reflecting objects ([British Association of Perinatal Medicine, 2008](#); [Doyle et al. 2010b](#); [Vohr et al., 2012](#)), or unable to fixate and follow a light with either eye ([Serenius et al., 2013](#)). Definitions of “moderate” hearing and vision impairment differ among studies.

Neurodevelopmental Impairment—Difficulties and Realities of a Composite Outcome

Neurodevelopmental impairment is a composite outcome, combining criteria and cut points from several domains as presented above, including neuromotor, cognitive, hearing, and vision. The relative prevalence of each of these outcomes is not consistent, and rates of each outcome may respond differently to an experimental therapy. This necessarily leads to a number of difficulties in overall interpretation, as well as challenges in generalizability and counseling. Use of composite outcomes during counseling in the prenatal or postnatal setting may not be meaningful to parents and families. The value of each of the components may vary broadly for each individual family, outcomes may be conceived differently, and statistics are probably difficult to grasp ([Janvier et al., 2012](#); [Dupont-Thibodeau et al., 2014](#)).

In addition, significant center variation in 18- to 22-month neurodevelopmental outcomes has been demonstrated even after adjustment for demographic variables, prenatal interventions, and neonatal clinical factors, thus presenting challenges to accurate counseling from multicenter datasets ([Vohr et al., 2004](#)). Unfortunately, robust data from a single center on outcomes of specific high-risk groups are generally unavailable. Furthermore, the largest contributing component to the composite outcome is that of “cognitive” delay or impairment. As explored previously and discussed in more detail later in the section [School Age Outcomes After Prematurity](#), developmental tests at 18 to 30 months are intended to assess cognitive abilities. However, in children born at extremely low birth weight (ELBW) and EPT, scores on these early administered tests predict cognitive scores at school age poorly ([Hack et al., 2005](#); [Roberts et al., 2010](#); [Schmidt et al., 2012](#); [Spencer-Smith et al., 2015](#)).

Death or NDI at 2 to 3 years is a primary or main secondary outcome in a substantial majority of clinical trials and prospective studies in neonatal medicine, particularly for EPT infants ([Marlow, 2014](#)). This combination is understandable because death and NDI are competing outcomes; it is assumed in this context that adverse outcomes (death and NDI) will not be influenced in opposite directions by an intervention and ideally that components of the combined outcome will carry similar value; these tenets may not always be true. Because the incidence of the composite outcome is greater than any individual component, death or NDI may also be a logical statistical choice for powering a trial; however, it may not be the most biologically plausible target. Moreover, although neurodevelopmental outcome at 2 to 3 years is critically important for any prospective observational study or clinical trial of high-risk infants, it may not be the most appropriate primary outcome for every trial.

Limitations and Challenges to Interpreting Early Neurodevelopmental Outcomes Studies

As described previously, early childhood follow-up visits for high-risk infants at 18 months to 3 years typically assess outcomes in multiple domains. Although these evaluations are important and informative, interpretation and comparison of studies are difficult. Many studies report outcomes by categories and frequently include *any* adverse finding to yield an “impaired” or “unimpaired” status. The definitions of “adverse” outcomes may not be consistent across studies; indeed, the definitions of the individual components of “impairment” such as CP, blindness, deafness, and developmental delay often differ across studies. Furthermore, not all prospective studies have enrolled contemporaneous term, NBW controls. Comparing test scores from a VPT or EPT study group with standardized norms instead of scores from a peer, term-born control group has been demonstrated to substantively limit the relevance and veracity of the findings and may have important public policy and resource implications (Marlow et al., 2005; Doyle et al., 2010b; Msall, 2010a; Aylward and Aylward, 2011).

Very early childhood developmental and neurologic outcomes evaluations should only be considered as a first step to comprehensive follow-up; assessments into school age, adolescence, and adulthood are critically important to understand the lifetime trajectory and functional and societal outcomes of former high-risk infants (Hack, 2009; Hack et al., 2012; Saigal et al., 2016). Concerns regarding changes in cognitive abilities over time, and an increasing recognition that physical and environmental effects as well as early intervention approaches may modify recovery, underscore the need for later assessments. Some neurocognitive, executive function and behavioral challenges may only be detected at school age; even recognizing that such learning and attention problems may occur in preterm infants is a critical step to ensuring adequate support and services for families and teachers to help children achieve their best possible outcomes. Evaluation of neuromotor outcomes throughout childhood is also critical. Although most toddler-age and very early childhood outcome studies focus narrowly on the diagnosis of CP, later neuromotor and coordination problems, such as DCD, are prevalent among school-age children born EPT compared with term and can be associated with other functional challenges and academic difficulties. Furthermore, parental perceptions of DCD are not reliable, yet interventions may be able to remediate the functional limitations of DCD, reinforcing the importance of ongoing clinical assessments throughout childhood (Roberts et al., 2011).

Similarly, there are substantial concerns regarding the ability of developmental or cognitive tests at toddler age, particularly the BSID, to detect developmental delay when using standardized test norms. In a group of EPT and ELBW infants at 2 years corrected age, Anderson et al. (2010) found mean BSID-III cognitive scores of 96.9 and motor scores of 100.4 but also substantially higher than expected scores among a term-born control group. If normative BSID-III cut-point criteria alone were applied to the scores of this cohort, it would severely underestimate moderate-to-severe cognitive and motor delay relative to the control group. Vohr et al. (2012) compared mean BSID-II versus BSID-III scores at 18 to 22 months corrected age for prematurity among infants less than 27 weeks' EGA born in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network (NRN) hospitals over two adjacent periods and found mean cognitive composite scores on the BSID-III to be 11 points higher than mean BSID-II MDI scores. Even after adjusting for

differences between groups, BSID-III was a significant factor in a perceived decrease in neurodevelopmental impairment in the more recent time period. Dilemmas also exist with regard to meaningful utilization of BSID-III motor composite and fine motor scaled score normative data and cut points in the context of other gross motor assessments at 18 to 24 months corrected age and the value of these early evaluations to predict later outcomes and intervene appropriately (Duncan et al., 2015). In a prospective, longitudinal EPT cohort from the Victoria Infant Collaborative Study Group (VICS Group), the BSID-III motor scale normative cut points for impairment at 2 years seriously underestimated rates of motor impairment at 4 years (Spittle et al., 2013b). In addition, although the BSID-III cognitive and language scales at 2 years were associated with cognitive functioning at 4 years as assessed by DAS-II, developmental delay at 2 years as determined by BSID-III reference data and normative cut points had low sensitivity in predicting future cognitive, verbal, and nonverbal reasoning impairments at 4 years on the DAS-II (Spencer-Smith et al., 2015). All of these findings have important implications for resource availability and public policy. In countries, states, or regions without specific policies advocating for ongoing, longitudinal assessments and services for children born EPT, the 2-year or 3-year evaluation may be the final opportunity to identify challenges before transitioning to the school system. If ongoing needs are determined only by scoring below a normative cut point on the BSID-III, many children at significant risk for future impairments could be left behind.

Despite these many challenges and provisos, a substantial body of literature exists on early neurologic and cognitive outcomes. An understanding of the range of initial neurodevelopmental outcomes, and the factors associated with adverse outcomes, is crucial for both the family and medical care team. In later sections of this chapter we review early neurodevelopmental outcomes of recent high-risk cohorts, including those born EPT and selected groups of high-risk late preterm and term infants.

Focus on Functional Outcomes

The WHO has defined “disability” as an umbrella term, covering impairments, activity limitations, and participation restrictions. An impairment is a problem in body function or structure; an activity limitation is a difficulty encountered by an individual in executing a task or action; and a participation restriction is a problem experienced by an individual in involvement in life situations. According to The World Report on Disabilities (WHO and World Bank, 2011), approximately 95 million infants, children, and youths 0 to 14 years of age worldwide (5%) live with a disability, of whom 13 million (0.7%) are considered to have severe disabilities. Nearly 800 million (~16%) individuals more than 15 years old live with a disability. The WHO International Classification of Functioning, Disability, and Health (ICF) provides standard language and a framework for the description of health and health-related states that are focused on functioning rather than diagnosis alone (WHO, 2001). It is a classification of health and health-related domains that describes what a person with a health condition can do in a standard environment, as well as how he or she can perform in his or her usual environment. These domains are classified from body, individual, and societal perspectives organized in two parts, each comprising two components. Part 1—Functioning and Disability—includes Body Functions and Structures and Activities and Participation; Part 2—Contextual Factors—incorporates Environmental Factors and Personal Factors. The ICF is meant to

be universally applicable and useful in a range of different sectors, including individual assessments, public policy, and research.

The focus of the ICF is on health and functioning, rather than on disability. In most studies and approaches, particularly in early childhood and even through school age, impairments are identified through tests or examinations, and an individual is classified with regard to that finding alone. In contrast, the ICF approach is to measure functioning in society, regardless of underlying impairments. This allows for a broader view than a traditional classification of health and disability. The ICF shifts the focus from diagnosis or label to impact on function, which may be affected by environment, intervention, and other factors.

In 2011, the WHO approved a “derived” classification, the International Classification of Functioning, Disability and Health for Children and Youth, which conforms to the common classifications of the ICF, with a goal of creating a comprehensive, life-span approach to describing health and functioning. However, attempts to apply these functional outcome classification approaches to very early childhood follow-up studies of high-risk infants have been limited, with some notable exceptions, including Msall and colleagues, who have championed the framework of function, even at early preschool age, as a highly relevant and measurable outcome (Msall, 2005). Among the several instruments available, the Vineland Adaptive Behavior Scale (VABS) is an interview survey for assessing adaptive behavior (Sparrow et al., 2005). In children less than 6 years old, the domains include communication (receptive, expressive language), daily living skills (self-care/personal), socialization (interpersonal relations and play), and motor skills (gross and fine). There is a classroom edition for children 3 years 0 months to 12 years 11 months. The Pediatric Evaluation of Disability Inventory (PEDI) assesses self-care, mobility, and social functional activities in children 6 months to 7 years (Feldman et al., 1990) and has been used extensively in children with severe perceived or known disabilities including those with CP and other physical impairments. The Functional Independence Measure for Children (Wee FIM) is an evaluative measure of basic functional skills that consists of 18 items encompassing three subscales: self-care, mobility, and social cognition. The Wee FIM has been used in children aged 2 to 7 years, including high-risk infants such as those born EPT and those with significant medical risk factors (Ottenbacher et al., 1999; Msall, 2010b). This instrument has been shown to have excellent concurrent validity with the VABS and PEDI and responsiveness to change over time (Msall, 2005). Such instruments are essential for understanding the functional impact of extreme prematurity and critical neonatal illness over the life course.

Outcomes of Preterm Infants Across the Life Spectrum

Early Neurodevelopmental Outcomes of Extremely Preterm Infants

Early neurodevelopmental outcomes of several large cohorts of EPT infants around the world have been reported. These are summarized in Table 66.1 and presented in detail later.

The Victoria Infant Collaborative Study Group

The VICS Group has reported on a series of birth cohorts of EPT neonates born in the state of Victoria (Australia) from 1991 to 1992, in 1997, and in 2005 (Doyle and the VICS Group, 2004; Doyle et al., 2010). Neonates born alive at 22 to 27 completed

gestational weeks and surviving to follow-up received neurodevelopmental assessment at 2 years of corrected age (1991–1992, $n = 219$, 97% of survivors; 1997, $n = 149$, 99% of survivors; 2005, $n = 163$, 95% of survivors). Importantly, contemporaneous NBW controls >36 weeks’ gestation were also enrolled and evaluated. Children were evaluated for blindness, deafness (hearing loss requiring amplification or worse) and developmental delay (using BSID). Cognitive and language composite scores were obtained relative to the mean and SD for the NBW controls, rather than the normative test scores and cut points alone. Neurologic examination for CP was also performed, utilizing the GMFCS, describing “severe” CP as unlikely ever to walk and “moderate” CP as unable to walk at 2 years but likely to walk. Overall disability was considered “severe” for children with severe CP, blindness, or severe developmental delay; “moderate” with moderate CP, deafness, or moderate developmental delay; and “mild” with mild CP or mild developmental delay.

Neurodevelopmental outcomes of the 2005 VICS cohort at 2 years corrected age are shown in Table 66.1. Comparing the 1991 to 1992, 1997, and 2005 cohorts, adverse outcomes were not significantly different across eras, although those in 2005 were less likely to have most adverse outcomes. Of note, for the 1991 to 1992 and 1997 cohorts, rates of any CP were 11% and 12.1%, whereas for the 2005 cohort the CP rate had decreased to 9.8%. Similarly, the 2005 cohort had significantly lower rates of severe developmental delay (3.7%) and severe neurologic disability (3.7%) than the 1997 cohort (14.8% and 15.4%), who in turn had significantly higher rates of these problems than the 1991 to 1992 cohort (7.3% and 7.8%). Moderate or severe developmental delay and moderate or severe disability were also similar overall across cohorts, with a decrease noted between 1997 and 2005 but an increase from 1991 to 1992 to 1997 (moderate or severe developmental delay—1991 to 1992, 18.3%; 1997, 24.2%; 2005, 16%; moderate or severe disability—1991 to 1992, 21%; 1997, 28.2%; 2005, 20.3%). Given these findings, it is not surprising that the mean utility per survivor was higher (better) in 2005 than either of the previous two cohorts at each gestational week from 22 to 26 weeks. Quality-adjusted survival increased with each gestational week, was greater for the 1997 cohort compared with the 1991 to 1992 cohort, and was stable between 2005 and 1997. Focusing on the 2005 cohort, the BSID-III cognitive and language composite mean scores were much higher than would be anticipated for the EPT cohort (97.5 and 93.9) but also higher for the control cohort (108.9 and 108.2); developmental delay for the EPT group would have been greatly underestimated had they not been evaluated relative to a term control group. Nevertheless, more than half of the EPT 2005 cohort had no developmental delay (52.1%) and no disability (50.9%) at 2 years.

Thus these regional, population-based studies reveal that although survival rates and quality adjusted survival for 22- to 27-week EGA infants increased through the 1990s and appear to have stabilized through the 2005 cohort, rates of severe delay and disability at 2 years appear to have improved since the late 1990s. As described later in this chapter, these investigators have also published extensively on school-age, adolescent, and young adult outcomes (Hutchinson et al., 2013; Roberts et al., 2013; Burnett et al., 2014).

EPICure 2

The EPICure 2 Study is a population-based mortality, morbidity, and neurodevelopmental outcomes study (Moore et al., 2012a).

TABLE 66.1
Early Neurodevelopmental Outcomes: Selected Recent Extremely Preterm Cohorts

| Study group description | NICHD NRN (Hintz et al., 2011) | NICHD NRN (Rysavy et al., 2015) | VICS 2005 (Doyle et al., 2010) | Japan NRN (Ishii et al., 2013) | EPICure 2 (Moore et al., 2012a) | Swiss Cohort (Schlapbach et al., 2012) | EXPRESS (Serenius et al., 2013) |

^aFor VICS, DQ = developmental quotient compared with a contemporaneous NBW control group; for EPICure 2, predicted MDI BSID, 2nd ed, from Bayley-III; for EXPRESS, aggregated Bayley-III cognitive and language score information, with mean and SD relative to a contemporaneous 37–41 week GA control group; for Japan NRN, formal evaluation by the KSPD was available for only 318 participants.

^bFace-to-face study examiner evaluations occurred in 55.3%. Multiple imputation from complete perinatal, neonatal, and sociodemographic information estimated outcomes for the entire cohort.

^cDefined as no functional vision in one or both eyes.

^dIncludes 173 with informal assessments of developmental delay by pediatricians, without formal developmental testing.

^eData regarding CP and BSID-II scores were reported in Schlapbach et al. (2011).

BSID-II, Bayley Scales of Infant and Toddler Development II; BSID-III, Bayley Scales of Infant and Toddler Development III; DQ, developmental quotient; EGA, estimated gestational age; EXPRESS, Extremely Preterm Infants in Sweden Study; GA, gestational age; KSPD, Kyoto Scale of Psychological Development; MDI, Mental Developmental Index; NBW, normal birthweight; NDI, neurodevelopmental impairment; NICHD, National Institute of Child Health and Human Development; NRN, Neonatal Research Network; SD, standard deviation; VICS, Victoria Infant Collaborative Study Group.

All neonates born at 22 to 26 1/7 weeks' gestation in the United Kingdom during 2006 were identified and data about death and morbidities were collected from the delivery room through hospitalization (Costeloe et al., 2012). Comparisons between EPICure 1 (Costeloe et al., 2000) (1995 birth cohort) and EPICure 2, both on short-term and neurodevelopmental outcomes, were limited to those 22 to 25 1/7 weeks' gestation and born in England. For EPICure 2, follow-up was hampered by changes in national research governance procedures in the United Kingdom and increased privacy restrictions by the National Health Service. Therefore tracking success was substantially limited in comparison with the previous study, and multiple imputation was therefore used to estimate outcomes of patients lost to follow-up. Follow-up assessments in EPICure 2 were with the BSID-III at a target age of 36 months, and at a target age of 30 months with the BSID-II in EPICure 1. In order to directly compare results from the two cohorts, combined BSID-III scores were converted to "predicted MDI" (Moore et al., 2012b). "Severe impairment" was defined as nonambulant CP (GMFCS III–V), blindness, profound hearing loss, or developmental quotient less than 3 SD below the mean for age. "Moderate impairment" was defined as ambulant CP (GMFCS 2), functionally impaired vision, hearing loss improved by aids, or developmental score of II–III SD below the mean.

Of the 1031 children in EPICure 2 who survived to follow-up (1041 survivors to discharge, 10 died after discharge), study examiners evaluated 576 (55.3%, median 34 months), and information from an additional 191 were available from local records (18.3%, median 25 months) (Table 66.1). The groups seen in person and not seen in person had similar baseline perinatal and neonatal characteristics, but socioeconomic factors differed; children from families with greater social disadvantage were less likely to have a formal study evaluation.

Among the EPICure 2 group with formal study evaluations, 75% were free from impairment or had mild impairment. Survival without disability for the entire EPICure 2 cohort, including imputed outcomes, among those admitted to the NICU demonstrated increases with each week in gestational age: 22 weeks, 5% (95% confidence interval [CI], 0%–26%); 23 weeks, 15% (95% CI, 10%–21%); 24 weeks, 30% (95% CI, 25%–35%); 25 weeks, 49% (95% CI, 43%–55%); 26 weeks, 62% (95% CI, 57%–67%). In addition, 66% had no hearing, vision, or communication disability, but only 36% of children were reported to have no developmental disability (BSID-II scores >85). However, robust comparisons are difficult, given that patient numbers were quite small, particularly for the less than 23 weeks' EGA group. This finding underscores the grave prognosis for survival among the most premature infants in this cohort; only 18% of less than 23 weeks' EGA neonates admitted alive to an NICU survived to discharge, compared with 48% of 25 weeks' EGA neonates.

Extremely Preterm Infants in Sweden Study

The Extremely Preterm Infants in Sweden Study (EXPRESS) cohort (birth year 2004–2007, <27 weeks' gestation) was followed to a median of 30.5 months, at which point BSID-III, neurologic examinations, and parental questionnaires were administered (Serenius et al., 2013). Of the 707 liveborn infants, 491 survived to follow-up (69%), 415 of 461 who were eligible for inclusion were assessed (90% follow-up rate), and 399 of these completed at least part of the BSID-III. Chart review was available for 41 additional children. The group was skewed to higher gestational age, with only 52 (11%) of the cohort born at 22 or 23 weeks' gestation. Of importance, a control group (37 to 41 weeks' gestation,

matched 2:1 with the preterm group) was recruited by random selection from the Swedish Medical Birth Registry. Severe disability was defined as BSID-III composite cognitive, language, or motor score greater than 3 SD below the mean relative to the control group, severe CP, or bilateral blindness or deafness. Moderate disability was defined as scores between 2 and 3 SD from the mean of any of the BSID-III scales, moderate CP, and moderate visual or hearing impairment. Mild disability was defined as scores between 1 and 2 SD from the mean of any of the BSID-III scales or mild CP.

As summarized in Table 66.1, of those children born EPT, 11.3% had moderate or severe cognitive disability by BSID-III, compared with 0.5% of controls. When considering cognitive, language, or motor scores, 15% of EPT and 3% of control had moderate disability, and 8.9% of EPT and 0.3% of controls had severe disability. The proportion of children with mild or no disabilities increased from 40% at 22 weeks to 83% at 26 weeks. There was a significant decrease in severe disabilities with each increase in gestational week, with an odds ratio (OR) 0.58 (99% CI, 0.39–0.86), $P < .001$. Overall, 42% of the EPT children in this group had no disability at 30 months, compared with 78% of control children. The majority of the 58% disabled EPT children had mild disability (31%). In further analyses, Serenius et al. (2015) explored whether intensity of perinatal care in regions across Sweden was associated with an increased risk of death or NDI at 2.5 years. The investigators found significant variation in obstetric and neonatal intervention practices. In regions with more aggressive perinatal intervention practices, the risk of death or NDI at 2.5 years was reduced, but only for the 22 to 24 weeks' group. Furthermore, there was no increase in NDI among survivors associated with more aggressive perinatal practices.

Japan Neonatal Research Network

The NRN of Japan reported outcomes of neonates born alive at 22 to 25 weeks' gestation during 2003 to 2005 (Ishii et al., 2013). Neurodevelopmental assessments were performed at 36 to 42 months chronologic age and consisted of a neurologic examination, functional assessment for vision and hearing, and cognitive evaluation by the Kyoto Scale of Psychological Development (KSPD). A developmental quotient (DQ) was derived, with a mean SD score of 100.6 ± 13.4 . NDI for this study was defined as any CP with GMFCS II–V, hearing impairment, visual impairment, or KSPD DQ score of less than 70. Profound impairment was defined as DQ less than 50 or CP with GMFCS IV or V.

Highlights of outcomes are shown in Table 66.1. Among 782 survivors at 3 years, 562 (71.9%) were evaluated in a follow-up visit. Follow-up rate among survivors declined over gestational age weeks, from 85.2% (23/27) for those born at 22 weeks' gestation, to 69.6% (240/345) for those born at 25 weeks' gestation. Among those examined, CP of any severity was diagnosed in 13.7%, and profound CP was seen in 8.2%, with higher rates noted at lower gestational ages (22 weeks, 17.4%; 23 weeks, 10.2%). Only 318 children were formally assessed by the KSPD (56.6% of those followed), whereas 173 were evaluated as delayed or not delayed by judgment of a pediatrician. If judged as "delayed" by a pediatrician, the DQ was assumed to be less than 50 for the purposes of this study; therefore rates of profound NDI or profound developmental delay may be overestimated when including these informal evaluations. Among those formally assessed, 34.6% had developmental delay of any severity (KSPD <70), and 11% were profoundly delayed (KSPD <50). For the children evaluated by a pediatrician only, 37% were assessed as delayed. Overall, when including any

assessment, NDI of any severity was reported for 208/491 (42.4%) of survivors. The composite outcome of death or any NDI was reported in 45.7% (483/1057) and death or profound NDI in 36.5% (386/1057).

Eunice Kennedy Shriver NICHD Neonatal Research Network Follow-Up Study Group

The NICHD NRN was initiated in 1986 as a multicenter effort in the United States with the main objective of providing a registry of uniformly collected baseline and morbidity and mortality data information to provide the basis for planning and implementing clinical trials. The NICHD NRN Follow-Up Study Group was later added to provide neurodevelopmental follow-up for trials and for those meeting NRN Follow-Up Study criteria, which now includes infants less than 27 weeks' gestation.

The NICHD NRN reported 18 to 22 months' corrected age outcomes of neonates inborn at an NRN site at less than 25 weeks' gestation during two epochs, 1999 to 2001 (epoch 1) and 2002 to 2004 (epoch 2) (Hintz et al., 2011). The follow-up visit included the BSID-II, as well as neurosensory and motor examinations. NDI was defined as MDI or PDI less than 70, moderate-to-severe CP (nonambulatory or requiring assistive devices), bilateral blindness (absence of functional vision in both eyes), or bilateral severe hearing loss requiring amplification. Profound NDI was defined as MDI less than 50, or GMFCS level 4 or 5. Unimpaired or minimally impaired was defined as having none of the following: moderate-to-severe CP, bilateral severe hearing loss or blindness, MDI or PDI less than 85. Follow-up rates for both epochs were approximately 90%. Only approximately 25% of both follow-up groups were composed of children born at less than 23 weeks' gestation.

Although results showed an apparent absolute increase in NDI from 50.1% to 58.7% between epoch 1 and 2, epoch was not found to be associated with NDI on multivariable analyses. Profound NDI was not significantly increased between epoch 1 (16.8%) and epoch 2 (17.5%). Rates of adverse outcomes were higher for children of less than 23 weeks' gestation than 24 weeks' gestation in both epochs, although patient numbers were small for rarer outcomes. Despite more aggressive perinatal management with increased cesarean section delivery (40.9%–48.8%) and dramatic reduction in postnatal steroid use (63.5%–32.8%) from epoch 1 to 2, no significant improvement in neurodevelopmental outcomes was observed. However, this study differed from others in that it narrowly focused on those less than 25 ½ weeks, and they were evaluated at an earlier age. These cohorts were also not population-based but rather representative of the academic centers in the NRN. As with previous analyses from this group (Vohr et al., 2004), center differences in outcomes were observed, suggesting that variability beyond what can be explained by perinatal and neonatal risk factors plays an important role in outcomes.

Between-hospital variation in survival and NDI at 18 to 22 months was further explored by Rysavy et al. (2015) among infants inborn at an NRN site before 27 weeks' gestation between 2006 and 2011. Impairment was defined similarly as above, with the exception that BSID-III cognitive scores of less than 70 were categorized as severe NDI, and scores of 70–84 were categorized as moderate NDI. Outcomes were evaluated in relation to hospital rates of "active treatment," defined as potentially lifesaving treatments initiated after delivery. For all infants, overall mean rates of survival without severe impairment were 3.4%, 17.9%, 44.7%, 61.1%, and 75.6% for 22, 23, 24, 25, and 26 weeks' gestation. However, there were significant differences among hospital rates

of active treatment for those born at 22 to 24 weeks, which accounted for a substantial proportion of variation in outcomes for children born in that gestational age range. The BSID-III was utilized during this study period, and there was no term control group.

Swiss National Extremely Preterm Cohort

The Swiss national EPT cohort study was a prospective, longitudinal study of infants live-born between 24 ½ and 27 ½ weeks' gestation in Switzerland between 2000 and 2008 (Schlapbach et al., 2012). Outcomes at 18 to 24 months corrected age were reported only for infants evaluated at sites utilizing the BSID-II. Severe disability was defined as CP with GMFCS level III–V, MDI or PDI less than 55, absence of useful hearing even with aids, or bilateral blindness. Moderate disability was defined as CP with GMFCS level II, MDI or PDI 55–69, hearing loss corrected with aids, moderately reduced vision but better than severe, or unilateral blindness with good vision in the contralateral eye. Favorable outcome was defined as survival without moderate or severe disability. Of 1266 liveborn infants, 844 survived to 18 to 24 months, of whom 684 had follow-up, including BSID-II testing (81%). For the cohort overall, 166 (24.3% of those with follow-up) were reported to have moderate disability, and 78 (11.4%) had severe disability. In a previous report from this group that included neonates born through December 31, 2007, CP and BSID-II scores were reported (Schlapbach et al., 2011). Of 541 children assessed at 18 to 24 months corrected age, 41 (7.6%) had CP of any severity. Of those with BSID-II scores, PDI less than 70 and MDI less than 70 were present in 99/485 (20.4%) and 99/527 (18.8%), respectively.

School-Age Outcomes After Prematurity

School-age survivors of prematurity have high rates of NDI, with CP rates of 9%–10% and cognitive disability rates of 4%–36%, depending on the population evaluated, outcome definitions, and age at assessment (Jarjour, 2015). Infants who have severe cognitive, motor, or neurosensory impairments in early years (2 to 3 years of life) are nearly always found to have moderate or severe impairments at school age (Marlow et al., 2005; Kodric et al., 2014). In the EPICure cohort of neonates born at less than 25 weeks' gestational age, 86% of children with severe disability at 30 months continued to have moderate or severe disability at 6 years (Fig. 66.1) (Marlow et al., 2005). More commonly though, school-age ELBW or very preterm survivors have more mild impairments that are difficult to classify correctly at earlier ages. These impairments include mild cognitive impairment (IQ 1–2 SD below the mean or 70–84); learning, emotional, behavior, motor coordination, and executive function disorders; and poor academic achievement.

Cognitive delay is the most common impairment in children who were born VPT. In a 2002 systematic review that included 1556 preterm infants and 1720 controls at 5 to 14 years of age, controls had significantly higher cognitive scores (mean difference 10.9 points) (Bhutta et al., 2002). The most immature infants have the highest risk for poor cognitive outcome; at 6 years 49% of boys and 32% of girls in the EPICure cohort (≤25 weeks' gestation at birth) had cognitive impairment (Marlow et al., 2005). Moderate and late preterm infants may even have an increased risk for poor cognitive functioning compared with full-term peers at school age (de Jong et al., 2012). Importantly, biologic factors such as sex, birth weight, and race are predictive of early

• **Fig. 66.1** Severity of disability at 6 years, based on classification at 30 months corrected age. Data are based on 236 children who were born at 25 or fewer completed weeks of gestation in the United Kingdom and Ireland in 1995. (Reproduced from Marlow N, Wolke D, Bracewell MA, Samara M; EPIcure Study Group. Neurologic and developmental disability at six years of age after extremely preterm birth. *N Engl J Med*. 2005;352:9–19. With permission from the Massachusetts Medical Society.)

cognitive outcomes (Linsell et al., 2015). However, as children enter school age, parental education is more predictive of cognitive outcome than biologic or perinatal factors. Furthermore, children with social advantages (two-parent household, educated parents, employed parents) demonstrate more cognitive gains through early childhood than those without social advantages (Manley et al., 2015).

Similarly, in 14 studies of school-age academic achievement, VLBW or VPT infants have scores on math, reading, and spelling tests that are 0.5–0.75 SD below term peers (Aarnoudse-Moens et al., 2009). Performance on academic assessments is also closely correlated with both birthweight and gestational age (Bhutta et al., 2002; Aarnoudse-Moens et al., 2009). Thus the most immature neonates born at less than 25 weeks' gestation have eight times higher odds of serious impairment in academic achievement than matched term controls (Marlow et al., 2005).

Measures of executive function (verbal fluency, working memory, and cognitive flexibility) also demonstrate decreases of about 0.5 SD between VPT or VLBW infants and term controls (Anderson and Doyle, 2004; Aarnoudse-Moens et al., 2009). These, however, do not seem to be correlated with birthweight or gestational age and may not be influenced by socioeconomic status (Anderson and Doyle, 2004).

At school age, children who were born preterm are more frequently reported by both their parents and their teachers to have behavior problems. VPT and even late preterm infants are more likely to have internalizing or externalizing symptoms on the Child Behavior Checklist than term counterparts (Bhutta et al., 2002; Delobel-Ayoub et al., 2009; Talge et al., 2010). Internalizing symptoms manifest as shyness, social maladaptation, anxiety, and withdrawn behavior (Anderson and Doyle, 2003; Aylward, 2005). It is critical to note that behavioral problems commonly occur in children with cognitive problems. In the French regional EPIPAGE cohort of children born at less than 33 weeks' gestation, there was a direct correlation between cognitive performance and

behavioral problems (Delobel-Ayoub et al., 2009). Infants with an IQ greater than 2 SD below the mean had 2.6 times higher odds of behavioral problems than those with an IQ less than 1 SD below the mean. However, cognitive disabilities did not explain the higher rates of behavioral problems in preterm-born children, because preterms remained at higher risk even after adjustment for cognitive performance. Behavioral problems in this cohort were more common in boys and in children with more complex medical histories, socioeconomic risk factors, and poor maternal well-being.

Neurobehavioral or psychiatric problems, including autism spectrum disorders (ASDs) and attention deficit-hyperactivity disorder (ADHD), are reported with higher frequency in school-aged former preterm children than in the general population (Bhutta et al., 2002). In the Extremely Low Gestational Age Newborn (ELGAN) study of neonates born before 28 weeks' gestation, 7% were diagnosed with ASD at school age (Kuban et al., 2016). Boys were twice as likely as girls to have ASD in this cohort. Moderate and late preterm infants may also be more likely to have ASD: one study reported that these children have a 1.55 higher odds of being diagnosed with autism by 10 years than full-term born children (Buchmayer, 2009). In preterm children, risk of ASD seems to be particularly increased among those who were small for gestational age, those with congenital malformations, low 5-minute Apgar scores, intracranial bleeding, cerebral edema, or seizures in the neonatal period and those born to mothers with preeclampsia (Buchmayer et al., 2009).

In a systematic review, preterm-born children had a relative risk (RR) of being diagnosed with ADHD of 2.64 (95% CI, 1.85–3.78) when compared with term-born children (Bhutta, 2002). In a large Swedish cohort, odds of ADHD at school age decreased with increasing gestational age until term corrected age (Lindström et al., 2011). Odds of ADHD were 2:1 among the most immature (23–28 weeks' gestation) infants and 1:1 among early term (37–38 weeks' gestation) infants. In the most preterm children, risk of ADHD does not seem to be significantly impacted by socioeconomic factors. However, sociodemographic risk—particularly low maternal education—may increase the risk for ADHD in moderately preterm children born to women with lower education (Lindström et al., 2011). Across the entire gestational age spectrum, school-age boys are about four times more likely to be diagnosed with ADHD than girls.

Because adverse developmental and neurobehavioral outcomes are considerably more common among preterm infants, it is essential for the pediatrician caring for former preterm school-age children to have a high index of suspicion for these problems. Early access to services is essential for optimizing outcomes. Many developmental and behavioral problems are more common among preterm-born male children than female children. Furthermore, while risk is highest in the most EPT infants, moderately preterm and late preterm infants are also at higher risk for adverse outcome at school age than term-born counterparts. School-age problems in the older preterm infant include fine and gross motor coordination problems, academic difficulties, attention problems, and need for special support in school (Huddy et al., 2001). As moderate and late preterm infants far outnumber VPT infants, it is critical to be aware of the likelihood of such outcomes and address any concerns or potential problems expeditiously. Cognitive and neurobehavioral problems in all high-risk children significantly increase special education costs and resource utilization at school age and strongly influence outcomes later in life.

Adolescent and Adult Outcomes After Prematurity

The advent of assisted ventilation and then surfactant and antenatal steroids in the late 20th century led to the first substantive generations of ELBW survivors. These surviving preterms are now adolescents and adults, whose outcomes are of importance not only to pediatricians but also to the adult physicians who will care for them for the remainder of the life course. The association between increased risk for all categories of adverse outcomes and decreasing gestational age continues into adolescence and adulthood. Medical sequelae of prematurity include impact on respiratory, cardiovascular, and renal function. Surviving ELBW infants are far more likely to have CP, blindness, and deafness compared with term-born matched controls (Doyle et al., 2010). As these are typically fixed impairments, rates in adulthood closely mirror rates at school age. Furthermore, over time, ELBW survivors have higher rates of other visual impairments, including refractive errors and late retinal detachment (Saigal et al., 2007). In adulthood, preterm survivors are more likely to receive disability pensions than term-born controls (Doyle et al., 2010).

VPT, VLBW, and moderately preterm-born adolescents are less likely to complete high school than adolescents born at full term (Hack et al., 2002; Lindström et al., 2007; Mathiasen et al., 2009). Furthermore, VLBW-born or VPT-born adults are less likely to seek education beyond high school (Hack et al., 2002; Cooke, 2004; Mathiasen et al., 2009). In adulthood, preterm-born cohorts have worse performance on tests of academic achievement than term-born controls (Hack et al., 2002). Few studies have closely evaluated cognitive function in preterm survivors. IQ is generally reported to be about 0.5 SD below term controls, but differences depend on the population studied. Predictors of adolescent and young adult IQ include maternal educational level, birthweight, and gestational age. For example, two studies have reported IQ of 87 versus 92 in adolescents with a birthweight of less than 1500 g and 94 versus 108 in adolescents with a birthweight of less than 1000 g, when compared with full-term controls (Hack et al., 2002; Lefebvre et al., 2005).

Even in adults without neurosensory or cognitive impairment, impairments in learning or executive function may interfere with educational and vocational achievement. Executive function deficits primarily involve impairments in response inhibition and mental flexibility (Nosarti et al., 2007). As discussed above, ASD and ADHD are more common among both VPT or VLBW children and even moderate/late preterm children; these disorders likely persist into adulthood (Mostert et al., 2008; Lindström et al., 2009). Reports of increased rates of schizophrenia, anxiety, and depression among preterm-born adults are inconsistent and conflicting (Hack et al., 2004; Mostert et al., 2008). In a large Norwegian study, RR of ASD was 9.7 times higher among adults born before 28 weeks' gestation as compared with those born at term (Mostert et al., 2008). Furthermore, RR of having a disorder of psychological development, behavior, and emotion resulting in a need to claim disability benefits was 10.5 times higher among those born before 28 weeks' gestation.

Overall, 23 to 27 weeks' gestation-born adults are 7.5 (95% CI, 5.5–10.0) times more likely to have a medical disability affecting the ability to work, as compared with term-born adults (Mostert et al., 2008). Among those who do not have a medical disability, VPT-born adults have significantly lower educational level, have lower income, and are less likely to get married and become parents (Mostert et al., 2008; Saigal et al., 2016). RR of having at least

one child among men born at 22 to 27 weeks' gestation is 0.24, RR among women is 0.33 (Swamy, 2008). Furthermore, preterm-born women are more likely to have preterm babies. Preterm-born adults are less likely to move outside their parents' home or cohabitate with a partner (Swamy et al., 2008; Mathiasen et al., 2009). Net income is significantly lower among VPT-born adults (Mathiasen et al., 2009; Saigal et al., 2016). On the positive side, preterm and VLBW-born adults are consistently reported to have lower rates of risk-taking, including smoking, alcohol, and drug use, and delinquent behavior (Hack et al., 2004; Saigal et al., 2016). However, this may be due to difficulty with socialization related to higher rates of internalizing behaviors.

Health-related quality of life is an important consideration as our most fragile and vulnerable patients age into adulthood (Dinesen and Greisen, 2001; Saigal et al., 2006). Only a few small studies have evaluated the long-term impact of prematurity on self-reported quality of life. Saigal and colleagues assessed health-related quality of life in a population of ELBW neonates born in 1977 to 1982 when the participants were 24 years old. Despite more functional limitations (cognition, sensation, mobility, and self-care), the ELBW participants did not report significantly different health-related quality of life from term-born controls. Later, in their thirties, the same cohort indicated lower self-esteem along with lower measures of multiple functional and health-related outcomes (Saigal et al., 2016). Similarly, in a small Danish cohort of young adults, objective quality of life (based on societal standards) was lower in those born VPT or with a chronic health problem (Dinesen and Greisen, 2001). However, subjective quality of life (based on individual life preferences and experiences) was not significantly different.

Thus the impact of prematurity on medical, developmental, psychological, and functional domains persists throughout the life course. It is critical to note that the most EPT (22–25 weeks' gestation) infants are only now surviving into adulthood. Adolescent and adult impact of survival at the limits of viability remain to be fully described in the current era of neonatal medicine.

Risk Factors for Adverse Outcomes in Preterm Infants

As described above, preterm infants as a group are at risk for multiple adverse outcomes throughout childhood and into adulthood. These risks are modified by patient characteristics, morbidities, and complications that occur during the neonatal period. Important neonatal morbidities that directly impact outcomes of preterm infants include brain injury, bronchopulmonary dysplasia (BPD), ROP, infection, necrotizing enterocolitis (NEC), and poor growth and nutrition. We end this section by addressing the impact of socioeconomic factors on outcomes.

Brain Injury

Cranial Ultrasound

Cranial ultrasound (CUS) has been used to image preterm infant brain injury since the late 1970s (Pape et al., 1979; Slovis et al., 1981). With the development of a standardized grading system for intracranial hemorrhage (ICH) (Papile et al., 1978), CUS quickly became and remains the neuroimaging standard of care for preterm infants (Ment et al., 2002). Although many still seem to rely heavily on simply the presence of grade 3 ICH, intraparenchymal hemorrhage (IPH), or cystic periventricular leukomalacia (PVL) to counsel families about the neurodevelopmental outcomes

of their preterm infants, the complexity of interpretation of CUS findings, and limitations of prediction of outcomes with any single neuroimaging or other finding, should give clinicians cause for prudence and careful consideration.

Virtually every major study of early neurodevelopmental outcomes among preterm and ELBW infants has confirmed a strong association between major CUS abnormalities and adverse neurologic and developmental outcomes. Definitions of CUS abnormalities as well as specific outcomes differ among studies; however, most consider IPH, ventriculomegaly (VM), or cystic changes, regardless of laterality or extent of the findings, to be severe abnormalities. In some, persistence of periventricular echodensity or “flaring” is included (de Vries et al., 2004, 2011; Ancel et al., 2006). The diagnosis reported in studies is frequently based on the results from a single CUS, either the “worst” or the “final” imaging study, but some prospective cohorts include serial imaging.

The focus of many studies has been on exploring the association of major CUS findings with CP. The ELGAN study followed infants of less than 28 weeks’ gestation from 14 institutions across five states in the United States from 2002 to 2004 (Kuban et al., 2009; O’Shea et al., 2009). Three study CUSs were performed during hospitalization and by multiple radiologists. BSID-II and standardized neurologic examinations for CP were performed at 2 years. The investigators found strong independent associations between CUS findings and CP. About half of the children with CUS echolucency or VM developed CP, and late occurrence of VM, bilateral echolucency, and IPH or PVL were strongly predictive of quadriplegia. However, almost half of the children with CP at 2 years had completely normal CUS, and the PPV of VM or echolucency for moderate or severe CP was poor. Isolated intraventricular hemorrhage (IVH) was not strongly predictive of CP.

Furthermore, CUS findings alone are poorly predictive of early developmental outcomes or later childhood cognitive and learning outcomes (Hack et al., 2000; Wood et al., 2005), and 30%–40% of those with “normal” CUS have neurodevelopmental challenges at 18 to 30 months (Laptook et al., 2005). The ELGAN study group showed that IVH was associated with increased risk for motor or developmental impairment at 2 years *only* when accompanied or followed by white matter lesions, highlighting the limited predictive value of both early CUS findings and IVH alone. In longer-term follow-up studies of the EPIPAGE cohort born at 24 to 28 1/7 weeks’ gestation, major CUS abnormalities remained strongly associated with CP (O’Shea et al., 2012). However, approximately 40% of those with major neonatal CUS abnormalities had no significant cognitive or learning challenges identified at 8 years, whereas 30%–40% of those with no neonatal CUS abnormalities had moderate-to-severe challenges (Beaino et al., 2010). This underscores the need for long-term surveillance through childhood for all born EPT. Nevertheless, in skilled hands, with meticulous technical attention and serial CUS imaging, much can be seen beyond ICH by CUS. In a single center, deVries et al. (2004) reported 76% sensitivity and 95% specificity of CUS abnormalities for CP at 2 years for patients of less than 32 weeks’ EGA. Of importance, among those with major CUS abnormalities who developed CP, approximately 30% were noted only after 28 days. Major CUS abnormalities were also not strongly associated with cognitive delay at 2 years. More recent findings from this group, using magnetic resonance imaging (MRI) at term equivalent age to refine specific CUS findings, have resulted in PPV and negative predictive value of 96% and 69%, respectively, for CP at 2 years among preterm infants (de Vries et al., 2011).

CUS is an operator-dependent modality, imaging procedures and views differ among institutions and studies, and there is no uniform approach to serial imaging protocols. Although interrater reliability and accuracy are very good to excellent for severe ICH, agreement is only fair or poor for subtler findings and PVL alone (Hintz et al., 2007). Cerebellar hemorrhage, a finding that may be missed without appropriate CUS views, is increasingly recognized to be associated with neurodevelopmental disabilities in children born preterm (Limperopoulos et al., 2007, 2014). Transient lesions may be missed, including echodense periventricular lesions or collapsing small cystic lesions (Pierrat et al., 2001). Isolated IPHs and of course large IVHs can be seen by CUS; however, not all “severe” hemorrhages can be considered equivalent in terms of association with early neurodevelopmental outcomes. Characteristics of the hemorrhage including laterality, midline shift, and extent of hemorrhage (Bassan et al., 2007; Davis et al., 2014), as well as the presence or absence of other adverse clinical factors (Merhar et al., 2012), impact prediction of neurodevelopmental outcomes.

Magnetic Resonance Imaging

Brain MRI has been used more extensively in recent years among preterm infants, both for research and for clinical indications. MRI provides a more comprehensive and detailed picture of the brain, with better delineation of deep structure and cortical injury. Potentially most importantly, MRI provides improved detection of white matter injury (WMI), which is common among preterm infants at term corrected age. Identification of WMI is critically important to understanding the structure–function relationship of the developing preterm brain, influences on later neuromotor and cognitive outcomes, and developing future neuroprotective strategies (Volpe et al., 2011). Subtle WMI on MRI is associated with reduced total brain and gray matter volumes, reduced cerebellar volume, and reduced basal ganglia and thalamic volume, which in turn are associated with childhood developmental impairments among preterm infants. These findings and others provide evidence that WMI in the preterm is associated with brain maturational disturbances, suggesting an overall link to impaired neural connectivity (Dean et al., 2014). Thus clinical investigations have focused on whether MRI may provide enhanced prognostic information.

Early studies attempting to compare term equivalent MRI with CUS predictive capabilities were limited by study size and different approaches to timing of imaging (Roelants-van Rijn et al., 2001; Mirmiran et al., 2004; Sie et al., 2005). Subsequently, WMI scoring approaches have been developed, and larger cohort studies have been published, among the first of which was a multicenter effort in Australia and New Zealand comparing serial CUS with near-term MRI findings and their association with 2-year outcomes in 167 infants of less than 30 weeks’ EGA (Woodward et al., 2006). This study demonstrated that moderate-to-severe WMI on near-term MRI was significantly associated with neuromotor delay and CP, independent of CUS findings and other risk factors. Increasing WMI severity was also related to lower BSID-II MDI scores, but an independent association of moderate-to-severe WMI with severe cognitive delay was not detected. However, CUS was assessed only with regard to early findings including grade of ICH and periventricular cystic changes, and a substantial proportion of infants with moderate-to-severe WMI by MRI did not have adverse 2-year outcomes. The NICHD Neuroimaging and Neurodevelopmental Outcomes study was a prospective study of early and late CUS and near-term MRI, including 480 infants of less than 28 weeks’

gestation, with outcomes including BSID-III assessed at 18 to 22 months (Hintz et al., 2015a). In multivariable models, both late CUS findings reflective of WMI and MRI findings of significant cerebellar injury remained independently associated with adverse neurodevelopmental outcomes. In models that did not include late CUS, MRI findings of both moderate-to-severe WMI and significant cerebellar lesions were independently associated with adverse outcomes. Early CUS findings were not associated with adverse outcomes when any late neuroimaging was taken into account. These results demonstrate the need to understand the evolution of brain injury over time rather than to rely on early findings. Similarly, in a prospective study of serial CUS and near-term MRI among neonates of less than 27 weeks' gestation in Sweden, associations between MRI findings and 30-month outcomes were shown, but the investigators determined that any substantial abnormalities on MRI were detected by the late CUS done on the same day (Skiöld et al., 2013). Diffuse excessive high signal intensity on near-term MRI has been shown not to be associated with adverse early childhood outcomes in several studies (Jeon et al., 2012; Skiöld et al., 2012).

In summary, despite what appears to be substantial experience with CUS and conventional brain MRI in preterm infants, controversies and questions remain as to which studies to perform, when to perform them and under what circumstances, and relative values in prognosis. These are not simple questions, as the "value" of additional information may vary by clinical circumstances and for individual parents and physicians (Janvier and Barrington, 2012). Cerebellar injury seen by MRI but not by CUS may be associated with higher risk for neurodevelopmental abnormalities (Tam et al., 2011; Hintz et al., 2015a), although the importance of punctate lesions remains unclear (Steggerda et al., 2013). Other studies have shown that MRI may provide additive information to predict neuromotor outcomes (de Vries et al., 2011), complementary to specific findings such as periventricular echodensities by CUS (Sie et al., 2005) or neurologic examination (Spittle et al., 2009; Skiöld et al., 2013). Neonatal sepsis and NEC have been linked with progressive or higher rates of WMI on MRI, and adverse 2-year outcomes associated with these morbidities (see later) may be mediated by WMI (Glass et al., 2008; Shah et al., 2008). Nevertheless, guidelines published in 2002 do not recommend near-term MRI for routine preterm infant neuroimaging (Ment et al., 2002), and a recent publication has suggested avoidance of routine term equivalent conventional brain MRI for screening purposes because there is "insufficient evidence that the practice improves long term outcomes" (Ho et al., 2015).

Future studies should further focus on identifying specific high-risk groups of preterm infants for which MRI would definitively improve prediction of neurodevelopmental outcomes and allow for risk stratification for neuroprotective or interventional studies. Investigations with advanced magnetic resonance techniques, including diffusion tensor imaging, functional connectivity MRI, surface morphometry, and volumetric methods, hold enormous promise to help to explore these questions (Anderson et al., 2015).

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD), typically defined as oxygen dependence at 36 weeks' postmenstrual age, is the most common morbidity of prematurity. BPD occurs in nearly half of neonates born at less than 28 weeks' gestation, and rates may be increasing over time (Stoll et al., 2015). BPD is associated with adverse

respiratory, developmental, educational, and health economic outcomes. EPT infants with BPD have increased coughing, respiratory medication use, hospitalizations, and impact of respiratory disease on the family at 18 to 22 months corrected age, compared with those without BPD (Stevens et al., 2014). A metaanalysis of pulmonary function testing in children born preterm with BPD, those born preterm without BPD, and children born at term demonstrated significantly decreased percentage forced expiratory volume in one second, with a further decrease in those with BPD (Kotecha et al., 2013). Several investigators have reported poor neurodevelopmental outcomes among infants with BPD, compared with preterm infants without BPD (Lifschitz et al., 1987; Portnoy et al., 1988; Grégoire et al., 1998; Majnemer et al., 2000; Roberts et al., 2009; Lodha et al., 2014; Schmidt et al., 2015). BPD is a consistent independent predictor of adverse developmental outcomes at 2 and 5 years (Schmidt et al., 2012). The adjusted odds ratio for death or disability at 5 years is 2.3 (95% CI, 1.8–3.0) times higher among very preterm born children with BPD than among those without BPD (Schmidt et al., 2015). Reports of cognitive outcomes at 8 years suggest that preterm-born children with BPD have lower IQs than those without (Robertson et al., 1992; Hughes et al., 1999).

Multiple large randomized trials have attempted to decrease rates of BPD in EPT neonates by applying interventions or drugs either in the delivery room or during the neonatal hospitalization. While some interventions or medications successfully decrease rates of BPD few have demonstrated improved developmental outcomes. Vitamin A reduces BPD or death in ELBW infants (RR 0.89) but does not improve developmental outcomes at 18 to 22 months (Ambalavanan et al., 2005). Postnatal corticosteroids reduce BPD but significantly increase risk for CP if given in the first 4 days of life. Use of corticosteroids after 7 days of life reduces BPD without increasing risk for CP (Halliday et al., 2003a, 2003b). Caffeine reduces BPD at 36 weeks, CP at 2 years, and severity of motor impairment at 5 years (Schmidt et al., 2006, 2007, 2012). In multiple randomized trials, surfactant therapy for respiratory distress syndrome reduces both air leak syndromes and mortality (Bahadue and Soll, 2012). It may reduce mild disability at 1 year but does not reduce moderate or severe disability at 1 year or any adverse outcomes at 2 years (Sinn et al., 2002).

Lastly, although antenatal corticosteroids reduce many complications of prematurity, including mortality and respiratory distress syndrome, it is unclear whether they improve rates of chronic lung disease (Roberts and Dalziel, 2006; Carlo et al., 2011). In the most immature (≤ 25 weeks' gestation) infants, antenatal steroids may increase rates of BPD, perhaps by leading to increased survival of high-risk infants (Carlo et al., 2011). Yet, prenatal steroid treatment is associated with a reduction in developmental disability or developmental impairment in childhood survivors (Roberts and Dalziel, 2006; Carlo et al., 2011). This includes decreased rates of cognitive impairment and CP among infants of less than 25 weeks' gestation who are exposed to prenatal steroids (Carlo et al., 2011).

Numerous neonatal trials have evaluated various methods of respiratory support in the delivery room and during the hospitalization. Early extubation to or complete reliance on noninvasive support such as continuous positive airway pressure (CPAP) has become standard of care (Pfister and Soll, 2012). However, none of these respiratory interventions has led to significant improvements in developmental outcomes (Vaucher et al., 2012).

Retinopathy of Prematurity

ROP occurs in about 60% of neonates born at less than 28 weeks' gestation in the United States, and stage 3 or higher ROP disease occurs in about 15% of those neonates (Stoll et al., 2015). Incidence of both ROP and high-grade ROP possibly requiring treatment increase significantly with decreasing gestational age (Stoll et al., 2015). With the evolution of cryotherapy, laser therapy, and antivascular endothelial growth factor (VEGF) pharmacologic treatment, blindness caused by ROP in the developed world is now rare. Nevertheless, on a global level, as many as 20,000 children annually are blind from ROP (Blencowe et al., 2013). Prematurely born children who are treated for ROP are at clear risk for long-term visual morbidities. However, infants with ROP that do not require therapy or lead to blindness are also at risk for long-term visual problems. At a 6.5-year follow-up of the Swedish EXPRESS cohort of neonates born at less than 27 weeks' gestation, 38% had at least some ophthalmologic abnormality, including blindness, strabismus, and refractive errors (Hellgren et al., 2016). Visual problems were strongly associated with ROP treatment and lower gestational age.

In addition to visual disabilities, severe ROP is associated with important nonvisual disabilities. At 5 years, stage 4 or 5 ROP or treated ROP is an independent predictor of poor neurodevelopmental outcome (Schmidt et al., 2015). This effect is similar in magnitude to and additive to the risks associated with severe brain injury or BPD (see earlier). These infants have more than four times higher odds of motor and cognitive disability than infants without severe ROP (Schmidt et al., 2014). In addition, they are more likely to have impairment in multiple domains.

The primary strategy utilized by neonatologists to reduce ROP has been restriction of supplemental oxygen. In a metaanalysis of five oxygen saturation targeting trials in EPT infants, targeting lower oxygen saturations (85%–89%) as compared with higher oxygen saturations (91%–95%) was associated with a somewhat lower risk of ROP (risk ratio 0.72, 95% CI 0.50–1.04) (Manja et al., 2015). Offsetting this potential benefit, the low saturation targeting strategy was also associated with an increase in risk of death before discharge (risk ratio 1.18, 95% CI 1.03–1.36) though not a significant difference in death by 18 to 24 months. Thus careful targeting of oxygen saturations alone is insufficient to eliminate risk of ROP in EPT infants, and low oxygen saturation targeting is unlikely to prevent enough ROP to justify potential risks.

The effect of ROP treatment itself may also have important implications for both visual and developmental outcomes. Laser therapy is the current standard treatment, but injection of anti-VEGF agents is increasingly used to treat acute ROP. In one small randomized trial, an anti-VEGF agent appeared to be superior to laser therapy for treatment of Zone 1 ROP (Mintz-Hittner et al., 2011). However, because of concerns about systemic absorption of the drug, late proliferative vascular changes that lead to retinal detachment, and only minimal differences in refractive outcomes at 2.5 years in the Mintz-Hittner et al. (2011) trial, neonatologists and ophthalmologists remain apprehensive about use of these drugs (Darlow, 2015). Such concerns are augmented by a small 2016 case series of 2-year outcomes in infants treated with laser, anti-VEGF drug, or both (Lien et al., 2016). Infants treated with both therapies had significantly higher rates of mental and psychomotor impairment on the BSID-II at 2 years than infants treated with laser. There was no difference between the laser and anti-VEGF-treated infants. Further research is needed to identify both novel

strategies for prevention of ROP as well as treatments that are safe and lead to improved visual outcomes without increasing adverse developmental outcomes.

Infection

Preterm infants are at high risk for both perinatally acquired and postnatally acquired infections. Due in large part to intense efforts to reduce iatrogenic late-onset sepsis, rates of neonatal infection have fallen in recent years. Nevertheless, about a quarter of EPT infants (born ≤ 28 weeks' gestation) have culture-positive sepsis while in the NICU (Schlapbach et al., 2011; Stoll et al., 2015). Similar to other neonatal morbidities, risk for late-onset sepsis increases significantly as gestational age decreases. Infection is associated with poor growth, and poor head growth in particular, which is an independent predictor of adverse outcome in preterm infants (see later) (Ehrenkranz et al., 2006). Furthermore, infection is associated with increased risk for low cognitive performance, CP, and vision impairment at 18 to 22 months (Stoll et al., 2004; Schlapbach et al., 2011). When adjusted for multiple factors predictive of CP, 2-year-old children with a history of extreme prematurity and confirmed sepsis have more than three times higher odds of CP (Schlapbach et al., 2011). By 5 years of age, both early-onset and late-onset sepsis in VPT infants are associated with significantly increased odds of CP but may not be associated with cognitive impairment (Mitha et al., 2013).

Infants with candida sepsis and/or meningitis and infants with bacterial meningitis experience the most significant increase in risk for poor developmental outcomes in early childhood (Bassler et al., 2009; Adams-Chapman et al., 2013). Ultimately, however, the overall risk for neurodevelopmental impairment (any one of cognitive impairment, CP, or vision or hearing impairment) associated with neonatal infection is slightly less significant than risks associated with severe IVH, ROP, or BPD (Bassler et al., 2009; Schlapbach et al., 2011).

Necrotizing Enterocolitis

NEC is diagnosed in about 7%–13% of neonates born at less than 28 weeks (Stoll et al., 2015). Infants with NEC are at increased risk for death, cognitive delay, CP, severe vision or hearing impairment, and the composite outcome of developmental impairment at 18 months (Schulzke et al., 2007; Bassler et al., 2009). In one large observational study, nearly all of this increase in risk for adverse outcome is associated with NEC requiring surgical intervention (Hintz et al., 2005). Surgical NEC and spontaneous intestinal perforation are associated with more than doubled odds of neurodevelopmental impairment among survivors (Wadhawan et al., 2014). However, similar to infection, the overall risk for adverse outcomes associated with NEC is less significant than risks associated with severe IVH, ROP, or BPD (Bassler et al., 2009).

Prenatal corticosteroid treatment leads to a significant reduction in NEC (Roberts and Dalziel, 2006; Carlo et al., 2011). Despite this reduction in NEC, as noted earlier, the impact of prenatal steroids on developmental outcomes remains uncertain. Exclusive maternal milk feeding reduces risk for NEC and improves developmental outcomes, although it is unclear that these two benefits are directly associated with one another. Several additional interventions show promise for further decreasing rates of NEC, including lactoferrin, probiotics, and use of donor milk when maternal milk is unavailable. However, there are currently insufficient data about either short-term efficacy or long-term impact on developmental

outcomes for any of these therapies to be adopted as standard of care (Sari et al., 2012; Akar, 2016).

Growth and Nutrition

A focus on growth and nutrition both in the NICU and after discharge is increasingly recognized as essential for optimization of longer-term developmental outcomes. In a large cohort study, neonates born between 501 and 1000 g were divided into quartiles of in-hospital growth velocity (Ehrenkranz et al., 2006). Increasing quartile of in-hospital growth velocity was associated with decreasing risk for CP and developmental outcomes more than 2 SD below the mean at 18 to 22 months corrected age, even after adjustment for other factors predictive of poor growth and development. Preterm infants who fail to thrive in the first 8 months after discharge have poor developmental outcomes compared with those who demonstrate catch-up growth or maintain an appropriate growth trajectory (Hack et al., 1982). Poor head growth in particular is highly predictive of adverse developmental outcomes until at least 8 to 9 years old (Hack et al., 1991).

Because of the strong associations between nutrition and growth during the first year of life and developmental outcomes, multiple strategies to improve growth have been evaluated. Early aggressive nutrition in the NICU currently includes early administration of parenteral nutrition, early enteral nutrition with maternal milk, and fortification of enteral milk feedings. While many of these strategies successfully improve growth, there is little evidence to date that these interventions improve developmental outcomes (Poindexter et al., 2006; Brown et al., 2016).

Socioeconomic Status

The critical importance of socioeconomic factors in the long-term development of high-risk infants cannot be overemphasized (Hack et al., 1992). Socioeconomic factors that influence cognitive outcomes include parent education, having two parents in the household, neighborhood, and social and racial backgrounds (Aylward, 2005; Manley et al., 2015). Furthermore, these factors influence the chance that a child's cognitive status will improve over the first years of life (Manley et al., 2015). Similarly, adverse socioeconomic factors such as younger maternal age and poor maternal well-being are strongly associated with increased behavioral problems at 5 years (Delobel-Ayoub et al., 2009).

As high-risk children get older, perinatal factors have progressively less influence on outcome, while parental education remains highly important (Linsell et al., 2015). Older children with functional limitations are more likely to live in families with limited resources, have less access to health care, and are exposed to less healthy home environments (Hogan et al., 2000). Decreased access to necessary health care is usually due to cost. Therefore just as for biologic risk factors, social risk factors including poor parental education, single parent household, low social class, and maternal well-being must be taken into consideration when assessing an individual child's risk for adverse developmental and behavioral outcome.

Summary

In summary, multiple adverse events during the neonatal course can impact longer-term developmental risk. Each of these events is associated with a unique level of risk and may impact development in somewhat different ways. Furthermore, in some situations these morbidities may interact with one another to additionally increase risk. The most significant risk factors for poor developmental

• **Fig. 66.2** The probability of neurodevelopmental impairment (NDI) in the Caffeine for Apnea of Prematurity Trial participants ($n = 1514$) at 5 years corrected age, based on the number of neonatal morbidities. Morbidities included were severe brain injury, bronchopulmonary dysplasia, and severe retinopathy of prematurity. The error bars represent 95% confidence intervals, the sloping green solid line indicates predictions based on a fitted morbidity count model, and the horizontal black dotted line indicates overall probability of NDI in the entire cohort. (From Schmidt B, Roberts RS, Davis PG, et al. Prediction of late death or disability at age 5 years using a count of 3 neonatal morbidities in very low birth weight infants. *J Pediatr*. 2015;167:982–986. With permission from Elsevier.)

outcomes at least until 5 years of age are severe IVH, ROP, and BPD (Fig. 66.2) (Schmidt et al., 2015). Each of these morbidities is associated with a linear, additive increase in risk for adverse developmental outcome. Neonatal infection—particularly fungal infection and meningitis—and NEC—particularly surgical NEC—add to the prediction of poor outcome. Poor growth is independently predictive of adverse outcome. Additional neonatal factors that increase risk for poor outcome include surgical ligation of the patent ductus arteriosus, general anesthesia, seizures, serious pulmonary hemorrhage, small for gestational age, and congenital abnormalities. Lastly, the family's socioeconomic status is of increasing importance as children grow. Assessment of the number and severity of neonatal risk factors will aid in counseling of families about likely developmental outcomes and determination of possible need for services during early childhood.

Other Infants at High Risk for Adverse Outcomes

Though the primary focus of the current chapter is risk assessment and outcomes of preterm and low birth weight infants, select groups of late preterm and full-term infants have significantly increased risk for poor outcomes and are addressed below.

Hypoxic–Ischemic Encephalopathy

Infants with perinatal depression or HIE are at risk for poor outcomes because of a neurologic insult suffered around the time of birth. Diagnosis of HIE is made by a standardized neurologic

examination consistent with encephalopathy, history of an acute perinatal event, low Apgar scores, and evidence of acidosis from either the umbilical cord or an infant blood sample obtained soon after birth.

More than 1000 infants with moderate or severe HIE have been enrolled in randomized trials of therapeutic hypothermia or “cooling” for HIE. These trials have demonstrated that cooling significantly reduces mortality (RR 0.75, 95% CI 0.63–0.88) and decreases rates of survival with major disability at 18 months of age (RR 0.68, 95% CI 0.56–0.83) (Tagin et al., 2012). Benefits of cooling persist at least until school age. Follow-up of two randomized trials of therapeutic hypothermia for HIE reveals lower rates of death or severe disability, CP, and moderate or severe disability, in addition to improved motor function scores, at 6 to 7 years (Shankaran, 2012a; Azzopardi et al., 2014). Despite the success of this intervention, about half of children with moderate or severe HIE still die or suffer long-term neurologic impairment. CP is diagnosed in nearly 20% and developmental delay in more than 22% of surviving cooled infants (Tagin et al., 2012).

The relationships between several clinical factors and outcomes of infants with HIE have been studied. Certainly, the degree of encephalopathy based on the original clinical assessment is closely correlated with both risk for mortality and developmental outcome. Other early clinical signs predictive of poor longer-term outcome are administration of chest compressions for greater than 1 minute at birth, onset of breathing greater than 30 minutes after birth, and base deficit of greater than 16 at any time (Shah et al., 2006). Serial clinical examinations are more predictive of outcome than any single examination. Improvement in the clinical examination during cooling or by 72 hours of life and normal examination at discharge are associated with decreased rates of death or disability by 18 months (Gunn et al., 2008; Shankaran et al., 2012b).

Children undergoing cooling are often monitored with either electroencephalography (EEG) or amplitude-integrated electroencephalography (aEEG). Prolonged discontinuity on EEG is associated with brain injury on MRI and poor developmental outcomes (Dunne et al., 2017). Burst suppression, low voltage, and flat trace predict developmental outcomes at greater than 12 months (Awal et al., 2016). However, it is uncertain whether aEEG or EEG data add significantly to the initial clinical assessment based on severity of encephalopathy in the era of therapeutic hypothermia (Shalak et al., 2003; Shankaran et al., 2011). Particularly in cooled infants, serial evaluation of aEEG background may improve prediction of poor outcome just as serial clinical examinations improve prediction (Thoresen et al., 2010). About half of newborns with HIE have seizures on EEG (Boylan et al., 2015). When managed with cooling, infants with HIE have lower overall seizure burden and shorter duration of seizures. The majority of these seizures are subclinical. The AAP recommends that centers offering therapeutic hypothermia have monitoring with aEEG or EEG available (Committee on Fetus and Newborn et al., 2014).

MRI-detected patterns and extent of brain injury are predictive of developmental outcome both at 2 years and at school age in HIE (Shankaran et al., 2015). In particular, injury to the basal ganglia and/or thalami is highly predictive of poor outcome (Bonifacio et al., 2015). Interpretation of MRI findings depends on timing of the examination after birth, because sequelae of the initial insult may evolve over the first days to weeks of life. Infants treated with cooling are more likely to have normal MRI than those who are not cooled, but an MRI without abnormal findings does not guarantee “normal” developmental outcome after HIE

(Rollins et al., 2014). Therefore all hospitals that provide cooling should also be capable of providing longitudinal neurodevelopmental monitoring and care (Papile et al., 2014).

Congenital Heart Disease

Over the past several decades, improved surgical techniques and medical management have resulted in significantly improved survival rates for the 0.6%–0.9% of infants who are born with CHD (Marino et al., 2012; Latal, 2016). This has led to increasing interest in the longer-term developmental and quality of life outcomes of children and young adult survivors of CHD. Noncardiac complications of CHD include cognitive, academic, financial, and psychological problems. Prevalence of poor outcome increases with severity of the heart lesion (Wernovsky, 2006). Furthermore, children who have genetic abnormalities or prematurity in addition to CHD have increased risk for developmental delays compared with those without these confounding conditions (Fig. 66.3).

In children with CHD, gross motor problems are often evident in early infancy and during the toddler period but appear to improve over time. Rates of CP are low, especially in comparison with other high-risk groups such as EPT infants or full-term infants with HIE. Intelligence in children with a history of CHD is decreased from expected values by 5 to 10 points and is less than 70 in about 10%–20%. This is associated with increased rates of language and learning problems at school age, emotional and behavioral problems in up to 40%, visuomotor and fine motor coordination problems, and significant impact on executive function. Survivors of CHD often require habilitative services, including therapies and special education. As in adults who were born preterm, persistence of these problems over time is likely to impact academic achievement, employment, and quality of life.

• **Fig. 66.3** Relationship between severity of congenital heart lesion in children with and without syndromes and severity of neurodevelopmental impairment. (Modified from Wernovsky G. Current insights regarding neurological and developmental abnormalities in children and young adults with complex congenital cardiac disease. *Cardiol Young*. 2006;16:92–104. With permission from Cambridge University Press.)

Adverse neurologic or developmental outcome in CHD is associated with several factors that are known in the neonatal and perioperative period. Just as clinical examination in HIE is predictive of longer-term outcome, so too is a careful neurologic examination of the infant with CHD (Khalil et al., 2014). Neurobehavioral problems are often evident even before surgical palliation of the CHD. Seizures occur in more than 10% of infants who undergo bypass surgery and are associated with poor outcomes, including mortality (Clancy et al., 2005; Naim et al., 2015). Duration of intensive care stay is a strong risk factor for adverse cognitive outcome up to 8 years, likely because it is a surrogate measure of overall severity of illness in this population (Newburger et al., 2003).

Infants with CHD are often born with brains that are both small and immature for their gestational age, which is thought to lead to increased vulnerability during the perioperative period. On MRI imaging, brain injury is detected both preoperatively and postoperatively and predominantly consists of WMI. However, the degree of WMI has not yet been correlated with developmental outcomes in the CHD population (Latal, 2016). A 2012 position statement from the American Heart Association and the AAP stratifies children based on risk for poor outcome and suggests age-based approaches to surveillance, screening, and evaluation of children with CHD (Marino et al., 2012). Because the first generations of survivors of CHD are now entering adulthood, more work to describe the developmental, functional, and quality of life outcomes of CHD during adulthood is urgently needed.

Extracorporeal Membrane Oxygenation

ECMO is a lifesaving therapy for patients with severe cardiac or respiratory failure that cannot be managed with conventional medical therapies. Almost half of all patients treated with ECMO are neonates, and about three-quarters survive to discharge (Mok et al., 2016). Both survival and longer-term developmental outcome after ECMO depend on the original indication for ECMO, pre-ECMO course, and complications while on ECMO. Highest ECMO survival rates are in infants with meconium aspiration syndrome, and lowest survival rates are in infants with congenital diaphragmatic hernia. Lower gestational age and birthweight are associated with higher risk of both complications and mortality. The primary complication of concern while on ECMO is intracranial bleeding.

Children who were treated with ECMO are at higher risk for later respiratory morbidity; hearing loss; poor motor, cognitive, and visuomotor performance; and behavioral problems. A randomized trial of therapeutic hypothermia during ECMO failed to demonstrate any neuroprotective effects at 2 years (Field et al., 2013). However, without ECMO these children are likely to still be at high risk for many of these outcomes and are likely to have higher rates of mortality. For example, infants with congenital diaphragmatic hernias who do not undergo ECMO have lower developmental outcomes at 1 year than expected norms, and 13% have severe cognitive, motor, or language delays (Danzer et al., 2015).

Summary

In summary, infants in each of these high-risk categories should be referred for early intervention at hospital discharge. In addition, most should be followed throughout the early childhood years by a multidisciplinary neurodevelopmental follow-up clinic that is capable of comprehensive surveillance, screening, diagnosis, and management. Monitoring should include traditional cognitive and motor assessments, behavioral evaluations, and surveillance for

neurosensory deficits. This proactive approach will ensure that these high-risk infants achieve their greatest potential as they mature through childhood and adolescence.

Postdischarge Management of the High-Risk Infant

Discharge Planning for the High-Risk Infant

Proper discharge planning will ensure a smooth transition home from the hospital both for the high-risk infant and for the family. A parent conference to review the infant's hospital course and plans for discharge will provide an opportunity to discuss the infant's progress and goals for discharge, identify risk factors for developmental challenges, assess the parents' understanding, and make clear plans for discharge. In review of the infant's various risk factors, an honest but sensitive discussion about the range of possible outcomes will help put risk for neurodevelopmental disabilities into perspective. Parents should be reassured wherever possible and given opportunity to hope.

Discharge teaching includes routine well-baby care, cardiopulmonary resuscitation, use of any special equipment or medication, and anticipatory guidance about car seats, safe sleep, and other common topics. When infants are discharged on medication or equipment, parents must demonstrate safe administration of the medication and use of the equipment. A pediatrician must be identified before discharge, and the inpatient team must personally communicate all relevant data about the child's hospital course and postdischarge plans with the pediatrician. The AAP has established a policy for the screening and surveillance of developmental concerns in the primary care setting (AAP, 2006). Please see Box 66.1 for general recommendations for primary caregivers who care for high-risk infants after discharge. In addition, infants who have had complications during the hospital course may require ongoing subspecialty care from various specialists. Lastly, all high-risk infants should be evaluated on an intermittent basis by a comprehensive developmental follow-up clinic and early intervention program. These services are an essential part of the continuum of care provided to high-risk infants and their families.

Multidisciplinary Follow-Up Care for the High-Risk Infant

Criteria for referral of high-risk infants for comprehensive developmental follow-up vary widely, based on available resources, funding, and geography. The comprehensive developmental follow-up program serves several important functions. High rates of follow-up and consistent collection of outcomes data allow a follow-up program to provide the NICU with accurate local data for specific conditions. Close relationships with community health, educational, and social services promote coordination of intervention services, based on individual child and family needs. Most importantly, the follow-up program provides coordinated and comprehensive care that will help the family optimize the child's growth and development; help the child integrate into the family, school and community; and allow timely intervention when necessary to reduce future medical, social, and emotional costs. These goals are promoted by the recognition that each child is an individual with unique qualities, strengths, and challenges and that each family differs in background, social supports, finances, coping mechanisms, and expectations for their child's future.

• BOX 66.1 Considerations for the Primary Care Physician Caring for the High-Risk Infant After Discharge

1. **Growth** – Monitor weight, length, and head circumference in all children and especially in children with BPD. Follow feeding skills closely.
2. **Neurosensory** – Diagnostic audiology assessment by 24–30 months (Harlor and Bower, 2009). Continued ophthalmology screenings and evaluation postdischarge for children with or at risk for ROP (Fierson, 2013).
3. **Immunizations** – Routine immunizations according to birth date, rather than corrected age. Influenza immunization yearly for child and caregivers. Palivizumab for all high-risk infants and young children per AAP recommendations (AAP, 2014).
4. **Neurodevelopmental** – Screen for neurodevelopmental problems, including ADHD and ASD, behavioral problems, and developmental delays.
5. **Motor** – Perform careful neuromotor examination and refer to physical or occupational therapy if not meeting milestones or abnormal examination.
6. **Learning** – Refer for evaluation for learning and executive function disorders if children struggle in school.
7. **Sociodemographic** – Assess for sociodemographic factors that may adversely impact outcomes, including parental anxiety and depression. Provide access to social supports as indicated.

The appropriate evaluations for a follow-up clinic visit will change as the child grows, develops, and increasingly interacts with the environment. Recognition of impairments, disabilities, and handicaps relies in part on parental reports, an appreciation of normal variability in developmental patterns, and the examiner's assessment skills and ability to determine the significance of abnormalities or deviations from normal development. The foundation of each follow-up evaluation is one of the basic tools of medicine—the history and physical examination. The focus of the history is on behavior, including sleep, feeding, temperament and any behavioral concerns, and developmental milestones. The physical examination is expanded to include a neurodevelopmental evaluation with assessment of posture; muscle tone; primitive, protective, and deep tendon reflexes; and functional abilities (Amiel-Tison and Gosselin, 2001). A detailed, structured neurologic examination as early as full-term corrected age in high-risk infants is highly correlated with neuromotor outcomes at least until 1 year of age. Many multidisciplinary clinics include an early childhood psychologist who evaluates cognition, learning, and other functions either at all visits or at targeted visits—for instance, at 12 and 24 months corrected age.

Gross and fine motor abilities are evaluated to assess motor development and to screen for CP (see section on [Early Neurodevelopmental Outcome Assessments](#) earlier) and minor neuromotor dysfunction. Children with minor neuromotor dysfunction have mild or no delay and mild neuromotor abnormalities on examination. However, minor neuromotor dysfunction may still have significant functional impact, such as impact on speech, feeding, and motor coordination. As children get older, disorders of motor coordination (developmental coordination disorder) can influence ability to participate in activities in multiple domains, including home and school.

Motor problems are often the first to be recognized and are associated not only with later motor problems but also later cognitive disability (Allen and Capute, 1989). Cognitive and language problems are recognized later in the first or second year. Delay in language abilities can be related to cognitive delay, hearing impairment, language disorder, or ASD. The first step in evaluation of a child with apparent language delay is a diagnostic audiology evaluation (Harlor and Bower, 2009). Neurobehavioral problems may become apparent in toddler-age children; motor coordination, learning, and executive function disorders are generally recognized at school age. Once identified, problems should be addressed with parents, including a nonmedical description of any diagnoses and description of specific intervention strategies.

Assessment of development and timely acquisition of milestones in preterm infants raise the controversial question of whether to correct for the degree of prematurity. This issue is most important early in life and in the most premature infants. Therefore early in life, expectations and results of developmental assessments are “adjusted” for prematurity. As children grow, the difference between the adjusted and chronologic age becomes less significant, so correction is no longer as critical. Researchers and clinicians have different perspectives on when—if ever—to stop correcting for prematurity. Within an individual clinic, however, a standard should be set and followed by all clinicians for all patients.

Referral for Early Intervention Services

All preterm children and high-risk children with abilities in any domain that are consistently below expectations based on their age should be referred for early intervention. Eligibility for surveillance or services for high-risk infants or children differs by geography. In the United States, the Individuals with Disabilities Education Act requires states to provide early intervention services for infants and toddlers up to 3 years of age with developmental delays and with conditions that lead to developmental delays. However, states differ in definitions of delay, standards with regard to correction for prematurity, and services offered (Shackelford, 2006).

Infants may be referred to early intervention by the NICU, follow-up clinic, pediatrician, or family. Each child who is referred is entitled to a multidisciplinary assessment and a service coordinator to facilitate the assessment and services. Early intervention programs recognize the importance of (1) viewing each child as a unique individual, (2) evaluating not only needs but also strengths, (3) including the family in the planning process, and (4) coordinating all intervention services. The choice of interventions is determined by the individual child's developmental profile and health, the needs of the family, and available resources.

Early intervention helps ensure that children reach their maximum potential but does not necessarily prevent disability (Spittle et al., 2015). Research about the efficacy of early intervention

includes many different interventions, applied with different intensity, in different populations, and for different lengths of time. Hearing and visual impairments are responsive to early intervention, and early therapies can significantly improve long-term functioning and quality of life. In general, early intervention programs have been shown to have positive effects on developmental and neurologic outcomes for preterm infants during infancy and early childhood (Spittle et al., 2015). Specifically, early intervention is associated with improved behavioral outcomes, reduced anxiety and depression for primary caregivers, and cognitive benefits through preschool age. Importantly, early intervention programs focused on the parent–child relationship are more effective than programs focused on the child or the parent alone.

Early intervention has less of an impact on motor outcomes and no impact on rates of CP. However, a few recent small studies of focused, intensive, goal-oriented therapy for infants at high risk for CP have demonstrated improved motor outcomes (Prosser et al., 2012; Eliasson and Holmefur, 2015; Morgan et al., 2016). No long-term studies of such interventions for infants at risk for CP have been completed to date. Thus it remains uncertain whether any specific forms of early intervention or disability-focused therapies have significant long-term impact on functional motor outcomes at school or at home. However, once a child has a diagnosis of CP or DCD, targeted interventions are then aimed at prevention of further delay and compensating for deficits, to optimize the child's function and independence (Majnemer, 1998). A recent review of therapies for children with DCD identified that the task-oriented approach, which includes cognitive approaches with a focus on specific aspects of a motor skill, was an effective way of teaching motor skills in DCD (Smits-Engelsman et al., 2013). Continued research is essential to identify the best therapies, including timing, intensity, and duration, to optimize outcomes for preterm and high-risk infants and children.

Challenges to and Importance of Follow-Up

There is a growing reliance on complete evaluation and reporting of neurodevelopmental outcomes in prospective studies and trials and an increasing and appropriate recognition that it is crucial to fully understand outcomes beyond the initial hospitalization and even beyond early childhood. Yet, the challenges of following a cohort for years or decades and the potential barriers to achieving reliable results are numerous. Long-term follow-up requires time, dedication, and persistence from both follow-up staff and from families. Achieving a high follow-up rate is essential to limit bias. Some studies report that infants who fail to keep follow-up appointments, or are followed only with great difficulty, are more likely to have developmental impairment; however, a systematic review suggests just the opposite (Tin et al., 1998; Callanan et al., 2001; Guillén et al., 2012). Social and demographic disparities and population differences have been shown to be associated with increased attrition (Aylward et al., 1985; Guillén et al., 2012; Kuppala et al., 2012; Hintz 2015b), which is of concern not only because of the potential bias introduced but also because those children and families lost to follow-up could potentially benefit most from supports and services.

Nevertheless, depending on the group from which a cohort is drawn and the reason for its creation, questions related to generalizability of findings may be inherent, regardless of outstanding follow-up rates. Thus population-based or large regional-based cohorts such as EPICure (Marlow et al., 2005), VICS (Doyle et al., 2010), and the EXPRESS group (Serenius et al., 2013) may be

considered the ideal model of prospective observational studies of high-risk infants. Caution is advised when comparing outcomes of different cohorts over time, because of differences in the enrolled populations and attrition rates, changes in versions of or use of different instruments, and varying approaches to use of term control groups.

Outside the scientific framework of follow-up for research purposes, there is a substantial *clinical* need for high-risk infant follow-up. The purpose and potential value of this difficult undertaking are manifold. As survival of even the most extremely preterm and complex infants has improved, there is increasing recognition of the importance of neurodevelopmental outcomes, rather than short-term endpoints alone, as a measure of the impact of interventions and management strategies in the NICU. Much has been invested in assuring the survival of these high-risk infants and must be invested similarly to assure that all of these children reach their best potential. In addition to traditional quality improvement measures to decrease in-hospital morbidities that are associated with adverse neurodevelopmental outcomes, early detection, preventive care, and intervention programs inclusive of both infants and families hold the best promise for changing the trajectory of outcomes.

Within an ecologic framework, the home environment and relationships are the most immediate and proximal influences on child development (Bronfenbrenner, 1986). More distal factors, such as family income and broader community factors, influence children's development both directly and indirectly through interaction with other proximal environmental factors. In understanding the developmental systems approach and recognizing the profound potential to influence brain development, positive outcomes can be understood in terms of improvements in developmental pathways associated with parental sensitive–responsiveness and child participation in intensive intervention-oriented child care (Milgrom et al., 2010; Kolb and Gibb, 2011; Guralnick, 2012).

Without a doubt, implementing a comprehensive system of NICU-to-community early and preventive interventions for high-risk infants is a time-intensive and resource-intensive undertaking. But we are unlikely to truly transform long-term care and improve the lifetime outcomes of high-risk infants without such an investment in the future.

Breastfeeding

LYDIA FURMAN AND RICHARD J. SCHANLER

KEY POINTS

- Hospital policies must support mothers who intend to breastfeed and should reflect and incorporate the Baby-Friendly Hospital Initiative's Ten Steps to Successful Breastfeeding.
- Breastfeeding advocacy should reach into the community: breastfeeding is a public health issue with evidence-based health and economic benefits.
- All pediatricians must be knowledgeable about lactation management and be prepared to lead healthcare teams that support the breastfeeding dyad.
- Every home-going infant should receive medical care at a pediatric office that has seamless access to appropriately trained lactation specialists.
- Breastfeeding education and support should be offered by trained peers and medical health providers, both prepartum and postpartum, both in the community and in medical settings, and to the mother, her partner, and all in her support system.
- Changes in national health policy, such as availability of free lactation services and paid maternity leave, hold promise for reducing health disparities associated with breastfeeding rates.
- Each neonatal intensive care unit should have protocols and guidelines to support lactation for mothers of hospitalized neonates.

Exclusive breastfeeding through 6 months of age, with continued breastfeeding to 12 months and beyond, is recommended for all infants by the World Health Organization (WHO; <http://www.who.int/topics/breastfeeding/en/>), the American Academy of Pediatrics (AAP; <http://www.aap.org/breastfeeding/>), and other professional organizations (World Health Organization, 2002; AAP, 2015; ACOG, *Optimizing Support for Breastfeeding*, 2016). Successful lactation depends on supportive attitudes of pediatric and obstetric providers, evidence-based hospital practices, and the awareness that many mothers will need assistance to establish and maintain breastfeeding. Much information must be shared with new parents in the short postpartum hospital stay, so both prenatal and postdischarge breastfeeding education and support are essential. Caregivers should be trained to support and document breastfeeding, and newborns should have early follow-up at 3 to 5 days of age with a knowledgeable healthcare provider and continuing lactation help (AAP, 2015).

Rates of Breastfeeding in the United States

While breastfeeding was the norm in the early part of the 20th century, rates declined after World War II, likely because of women returning to the workforce as well as to the availability of commercial infant formulas. Recognition of breastfeeding benefits grew during the 1970s, and rates more than doubled in the United States from 24.7% in 1971 to 59.7% in 1984 (Wright, 2001). The US Centers for Disease Control and Prevention began monitoring annual breastfeeding rates through the National Immunization Survey (NIS) in 2001 and administered the first national survey of maternity practices related to breastfeeding, the Maternity Practices in Infant Nutrition and Care Survey, in 2007 (Breastfeeding Data and Statistics, 2017). These figures can be compared with the Department of Health and Human Services' Healthy People 2020 breastfeeding goals (Table 67.1); goals added for 2020 relate to reducing formula supplementation for breastfed infants, increasing the proportion of workplaces with onsite lactation support, and increasing the proportion of live births at facilities with best practices supporting lactation (to 8.1%) (Breastfeeding Data and Statistics, 2015; US Department of Health and Human Services, 2015). In 2011 the US Department of Health and Human Services issued *The Surgeon General's Call to Action to Support Breastfeeding*, which reviewed research on the multiple benefits of breastfeeding and described steps that family members, healthcare providers, researchers, employers, and communities can take to support breastfeeding (DHHS, 2011). While some states and population subgroups have met initiation and continuation goals, disparities related to race, ethnicity, age, and socioeconomic status have not been eliminated (CDC, 2015). Non-Hispanic African Americans and economically disadvantaged populations have the lowest breastfeeding rates for all measures at all infant ages, and women who are younger, unmarried, receive or are eligible for support from the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), and who have a lower educational level are less likely to initiate or continue breastfeeding (Table 67.2; CDC, 2015). Culturally specific feeding beliefs also influence breastfeeding choice (Cassidy and El Tom, 2015). An example from the Navajo culture is the belief that either negative or positive maternal emotions can be transmitted through breast milk (Wright et al., 1993). Disparities in breastfeeding rates are an important arena for public health initiatives (US Department of Health and Human Services, 2013).

TABLE 67.1**Healthy People 2020 Infant Feeding Goals and Rates of Breastfeeding in the United States 2004 to 2012**

| Healthy People 2020 Objectives | 2004 | 2006 | 2008 | 2010 | 2012 |
|--|---|------------|------------|------------|------------|
| Breastfeeding Goals | | | | | |
| 81.9% initiation postpartum | 73.1 ± 0.8 | 74.0 ± 0.9 | 74.6 ± 0.9 | 76.7 ± 1.2 | 80.0 ± 1.2 |
| 46.2% exclusive breastfeeding at 3 months | 31.5 ± 0.9 | 33.6 ± 1.0 | 34.3 ± 1.0 | 37.1 ± 1.4 | 43.3 ± 1.6 |
| 25.5% exclusive breastfeeding at 6 months | 12.1 ± 0.7 | 14.1 ± 0.8 | 14.6 ± 0.8 | 17.2 ± 1.2 | 21.9 ± 1.4 |
| 60.6% any breastfeeding at 6 months | 42.1 ± 0.9 | 43.5 ± 1.1 | 43.5 ± 1.1 | 47.5 ± 1.4 | 51.4 ± 1.5 |
| 34.1% any breastfeeding at 12 months | 21.4 ± 0.8 | 21.4 ± 0.8 | 21.4 ± 0.8 | 25.3 ± 1.3 | 29.2 ± 1.4 |
| Additional Goals | | | | | |
| 14.2% of breastfed infants within first 48 h | 23.5 ± 1.0 | 24.2 ± 1.1 | 25.1 ± 1.1 | 22.8 ± 1.4 | 19.1 ± 1.3 |
| 38.0% of workplaces with lactation support | (25% reporting in 2009 serving as the baseline; other data not available) | | | | |

Numbers represent the percentage of US children who were breastfed, by birth year, National Immunization Survey, United States (percent age ± half 95% confidence interval); see site for additional methodological details of the survey, and see <http://www.cdc.gov/breastfeeding/data/reportcard.htm> for annually updated breastfeeding rates.

Maternal, Infant and Child Health. <http://www.healthypeople.gov/2020/topics-objectives/topic/maternal-infant-and-child-health/objectives>; and Centers for Disease Control and Prevention. Breastfeeding among U.S. children born 1999-2005, CDC National Immunization Survey. http://www.cdc.gov/breastfeeding/data/NIS_data/index.htm.

• BOX 67.1 Ten Steps to Successful Breastfeeding

- Step 1: Have a written breastfeeding policy that is routinely communicated to all healthcare staff.
- Step 2: Train all healthcare staff in the skills necessary to implement this policy.
- Step 3: Inform all pregnant women about the benefits and management of breastfeeding.
- Step 4: Help mothers initiate breastfeeding within 1 hour of birth.
- Step 5: Show mothers how to breastfeed and how to maintain lactation even if they are separated from their infants.
- Step 6: Give newborns no food or drink other than breast milk, unless medically indicated.
- Step 7: Practice rooming-in—allow mothers and infants to remain together 24 hours a day.
- Step 8: Encourage breastfeeding on demand.
- Step 9: Give no pacifiers or artificial nipples to breastfeeding infants.
- Step 10: Foster the establishment of breastfeeding support groups, and refer mothers to them on their discharge from the hospital or birth center.

From the Baby Friendly Hospital Initiative “Ten Steps to Successful Breastfeeding for Hospitals” as outlined by UNICEF/World Health Organization. Available at <https://www.babyfriendlyusa.org/about-us/baby-friendly-hospital-initiative/the-ten-steps>.

Interventions to Support Breastfeeding Initiation, Exclusivity, and Continuation

In response to extensive formula marketing in the developing world with resulting high rates of infant morbidity and mortality, the World Health Assembly created the International Code of Marketing of Breastmilk Substitutes (1981) to promote ethical marketing of formula products (World Health Organization, 1981). In 1992 United Nations International Children's Emergency Fund and the World Health Organization (WHO) developed the Baby-Friendly Hospital Initiative (BFHI), an international program to promote breastfeeding-supportive policies for birthing hospitals (Box 67.1; Willumsen, 2013). The BFHI “10 steps” in combination with an “11th step,” the WHO International Code of Marketing of Breastmilk Substitutes, which protects against free provision and

advertising of breast milk substitutes (i.e., formula), effectively increased breastfeeding rates worldwide (World Health Organization, UNICEF and Wellstart International, 2009). Adherence to these evidence-based maternity practices significantly increases the likelihood of mothers initiating breastfeeding, exclusively breastfeeding, and breastfeeding through 6 months (DiGirolamo et al., 2008; Sinha et al., 2015; Yotebieng et al., 2015). While implementation of all ten steps is optimal, breastfeeding rates increase with the number of steps practiced, including with a single step, such as initiating breastfeeding within 1 hour of birth with skin-to-skin contact (Kramer et al., 2001; Philipp et al., 2001; Rosenberg et al., 2008; Moore et al., 2012; Olaiya et al., 2016). Possible expansion of a modified Ten Steps to Successful Breastfeeding program to neonatal intensive care units (NICUs) has been proposed (Nyqvist et al., 2013; World Health Organization, 2015). State health departments have begun to create programs to support Ten Steps to Successful Breastfeeding practices (e.g., <http://texastenstep.org/>), and the number of birthing hospitals designated as baby friendly (by Baby-Friendly USA Inc.) is increasing (Baby-Friendly, 2015).

Systematic reviews suggest that breastfeeding support is optimal when offered prepartum and postpartum and in multiple settings: essential interventions include counseling by peers and health providers, BFHI practices, and actions that mobilize community awareness (Sinha et al., 2015). Counseling and education in the home and family environment promote breastfeeding initiation, exclusivity, and continuation; family and social support alone, surprisingly, had no significant impact (Sinha et al., 2015).

WIC initiatives, including enhanced maternal food packages for breastfeeding mothers and peer counseling (Loving Support), hold promise, as do the Affordable Care Act mandates covering breastfeeding education and supplies and reasonable break time for “nonexempt” hourly employees to express milk (Sections 2713 and 4207) (Murtagh and Moulton, 2011; Hawkins et al., 2015). Workday strategies that include feeding the infant directly from the breast appear more effective than pumping only (Fein et al., 2008). However, maternal employment outside the home, in general, is associated with decreased breastfeeding initiation and continuation (Ogbuanu et al., 2011; CDC, 2016). Public policy changes can increase national breastfeeding rates: provision of paid maternity

TABLE
67.2

Rates of Any and Exclusive Breastfeeding by Sociodemographic Factors Among Children Born in 2012

| Sociodemographic Factors | n | ANY BREASTFEEDING | | | n | EXCLUSIVE BREASTFEEDING | |
|---|--------|-----------------------------------|--------------------------------|---------------------------------|--------|-------------------------------------|-------------------------------------|
| | | Ever Breastfed % ± Half 95% CI | At 6 Months % ± Half 95% CI | At 12 Months % ± Half 95% CI | | Through 3 Months % ± Half 95% CI | Through 6 Months % ± Half 95% CI |
| US National | 15,141 | 80.0 ± 1.2 | 51.4 ± 1.5 | 29.2 ± 1.4 | 14,768 | 43.3 ± 1.6 | 21.9 ± 1.4 |
| Race/Ethnicity | | | | | | | |

| No, but eligible | 1096 | 80.3 ± 6.7 | 58.2 ± 6.5 | 40.9 ± 6.0 | 1065 | 51.4 ± 6.5 | 29.7 ± 5.9 |
| Ineligible | 7304 | 90.5 ± 1.1 | 68.4 ± 1.9 | 41.6 ± 2.2 | 7096 | 56.8 ± 2.2 | 30.0 ± 2.2 |

The breastfeeding rates are based on dual-frame (landline and cellular telephone) samples from the 2013 National Immunization Surveys and the 2014 National Immunization Survey. See the survey methods for details on study design. Exclusive breastfeeding is defined as only breast milk—no solids, no water, and no other liquids.

^aRatio of self-reported family income to federal poverty threshold for number in household.

^bUnmarried includes never married, widowed, separated, and divorced.

CI, Confidence interval; WIC, Special Supplemental Nutrition Program for Women, Infants, and Children.

From National Immunization Survey, Centers for Disease Control and Prevention, Department of Health and Human Services (http://www.cdc.gov/breastfeeding/data/nis_data/rates-any-exclusive-bf-socio-dem-2012.htm). Sample sizes appearing in the National Immunization Survey breastfeeding tables are slightly smaller than the numbers published in other National Immunization Survey publications because in the Division of Nutrition, Physical Activity, and Obesity breastfeeding analyses, the sample was limited to records with valid responses to the breastfeeding questions.

leave for employed women increases breastfeeding exclusivity and duration, and longer maternity leaves are associated with increased breastfeeding initiation (Fein et al., 2008; DHHS, 2011; Ogbuanu et al., 2011; Breastfeeding Promotion and Employment, 2016; Huang and Yang, 2015; Nandi et al., 2016). The United Nations International Labor Organization recommends 18 weeks of paid maternity leave, a “reasonable goal” that could push the United States closer to Healthy People breastfeeding targets (DHHS, 2011; US Department of Health and Human Services, 2017).

The Evidence to Support Breastfeeding

More than 1 decade ago, exclusive breastfeeding through 6 months of age was identified as the most effective international preventive health intervention for children younger than 5 years, with the potential to prevent 13% of deaths of children younger than 5 years worldwide (Jones et al., 2003). Human milk has widely acknowledged benefits in high-, middle-, and low-income countries with respect to infant nutrition, infant survival, gastrointestinal function, host defense, neurodevelopment, and psychological well-being. The benefits of exclusive breastfeeding, as well as a “dose-dependent” effect of breastfeeding duration and of partial breastfeeding, are well documented (Sankar et al., 2015). Maternal health benefits increase with the number of months of lactation and are also well described (Chowdhury et al., 2015). There is insufficient evidence to endorse formula supplementation as a change in practice from exclusive breastfeeding (Becker and Remington, 2014). However, health providers can elicit parents’ perspectives about the challenges of exclusive breastfeeding and provide scientifically based guidance and personalized support, recognizing that any breast milk (including colostrum) gives a meaningful health benefit (Flaherman and Fuentes-Afflick, 2014). The success of the United Nations Millennium Development Goals, with a reduction in the number of deaths of children younger than 5 years from 12.7 million per year in 1990 to 5.9 million per year in 2015, is multifactorial, yet breastfeeding plays a large current and larger potential role (World Health Organization Media Centre, 2015). Exclusive breastfeeding (0 to 5 months) is increasing by 1% annually in the Millennium Development Goals–tracked countries, with median coverage of 39% (Requejo et al., 2015). Each of the 2030 United Nations Sustainable Development Goals, for example, “Zero Hunger,” can be linked to and supported by breastfeeding. The global societal and economic benefits of full breastfeeding are remarkable and are yet to be fully realized.

Studies Supporting Benefits of Breastfeeding

Methodological issues impact research on health outcomes related to breastfeeding. These include (1) duration of breastfeeding recall, which is inversely related to accuracy (Burnham et al., 2014), (2) use of standardized definitions for breastfeeding duration, exclusivity, and method of feeding (expressed or at breast), which facilitates comparisons (Noel-Weiss et al., 2012), (3) the need to identify and adjust for confounders such as socioeconomic status, (4) study design (e.g., retrospective or cross-sectional studies are weaker than prospective longitudinal ones), and (5) concerns for reverse causality. Since it is nearly impossible and undoubtedly unethical to randomize mothers to breastfeed or not, unmeasured confounding occurs; randomization by health system has been one alternative approach (Kramer et al., 2001; Yotebieng et al., 2015). The preponderance of evidence supports the benefits detailed in the following sections.

Nutritional Aspects

The human milk model is used to design the composition of breast milk substitutes, because the goal for infant nutrition through the first year is to mimic the body composition of the breastfed infant. Human milk has a dynamic nutrient composition that changes throughout lactation, over the course of a day, and within a feeding and differs between women. Components of human milk have multiple nutritional and immunologic functions. A reference tabulation of the composition of human milk comparing early and more mature milk is given in Table 67.3 (Picciano, 2001). In the first few weeks after birth, the total protein content of milk from mothers who deliver prematurely (preterm milk) is greater than that of milk obtained from women delivering at term (term milk), and the total protein content in both declines similarly to approach that in what is called *mature milk* (Ballard and Morrow, 2013). Milk protein content is not related to maternal diet but increases with maternal body mass index (BMI) (Nommsen et al., 1991).

The protein quality of human milk (whey 70%, casein 30%) differs from that of bovine milk (82% casein, 18% whey). Caseins are proteins with low solubility in gastric acid, while whey proteins remain in solution after acid precipitation. The whey protein fraction is more easily digested and promotes rapid gastric emptying. It also provides lower concentrations of phenylalanine, tyrosine, and methionine and higher concentrations of taurine than the casein fraction and serves as a model for enteral and parenteral amino acid mixtures. The major whey protein in human milk is α -lactalbumin. Lactoferrin, lysozyme, and secretory immunoglobulin A (sIgA) are specific immunoactive human whey proteins that resist proteolytic digestion and thus serve as a first line of defense by lining the gastrointestinal tract (Brandtzaeg, 2010).

The lipid system in human milk, responsible for providing approximately 50% of the calories in the milk, is structured to facilitate fat digestion and absorption. The lipid system is composed of an organized milk fat globule, bile salt–stimulated lipase, and a pattern of fatty acids (high in palmitic [C16:0], oleic [C16:1 ω 9], linoleic [C18:2 ω 6], and linolenic [C18:3 ω 3] acids) characteristically distributed on the triglyceride molecule (C16:0 at the 2-position of the molecule). That distribution is unique to human milk. When triglycerides are hydrolyzed in the intestine, free fatty acids are released. Palmitic acid, in particular, is a prevalent fatty acid that has a predilection to bind minerals such as calcium to form insoluble “soaps.” The soap formation therefore reduces fat absorption and mineral (calcium) absorption. The palmitic acid in human milk triglyceride, however, is mainly found at the 2-position. Human milk lipases hydrolyze the triglyceride molecule but leave the palmitic acid bound to the glycerol backbone. The resulting monoglyceride is well absorbed. The fat blends in formula must be modified to compensate for poor fat absorption, so they contain greater quantities of medium-chain-length fatty acids, which are absorbed passively, in an attempt to mimic the superior fat absorption from human milk.

The pattern of fatty acids in human milk is also unique in its composition of very long chain polyunsaturated fatty acids. Arachidonic acid (C20:4 ω 6) and docosahexaenoic acid (C22:6 ω 3), found in human milk but not bovine milk and added to formula, are constituents of retinal and brain phospholipid membranes and have been associated with improved visual function and, potentially, neurodevelopmental outcome (Koletzko et al., 2008). The fat content of milk varies with maternal diet and throughout the feed, with hindmilk (the last part of the feed) containing

**TABLE
67.3****Representative Values for Constituents of Human Milk**

| Constituent | Early Milk | Mature Milk | Constituent | Early Milk | Mature Milk |
|---|------------|-------------|--------------------------------|------------|-------------|
| Energy (kcal/L) | | 650–700 | Linoleic acid (C18:2 ω6) | 8.9 | 11.3 |
| Carbohydrate | | | Arachidonic acid (C20:4 ω6) | 0.7 | 0.5 |
| Lactose (g/L) | 20–30 | 67 | Water-Soluble Vitamins | | |
| Glucose (g/L) | 0.2–1.0 | 0.2–0.3 | Ascorbic Acid (mg/L) | | 100 |
| Oligosaccharides (g/L) | 22–24 | 12–14 | Thiamin (μg/L) | 20 | 200 |
| Total nitrogen (g/L) | 3.0 | 1.9 | Riboflavin (μg/L) | | 400–600 |
| Nonprotein nitrogen (g/L) | 0.5 | 0.45 | Niacin (mg/L) | 0.5 | 1.8–6.0 |

| Total ω6 fatty acids (%) | 11.6 | 13.06 | | | |

^aThe cholesterol content of human milk ranges from 100 to 200 mg/L in most samples of human milk after day 21 of lactation.

IgG, Immunoglobulin G; IgM, immunoglobulin M; Kcal, kilocalorie; sIgA, secretory immunoglobulin A.

Modified from Picciano MF. Appendix: representative values for constituents of human milk. *Pediatr Clin North Am.* 2001;48:263–272 and Schanler RS, Krebs N, Mass S, eds. *AAP/ACOG Breastfeeding Handbook for Physicians*. Elk Grove, IL: American Academy of Pediatrics; 2013:77.

two to three times more than the initial milk (foremilk) (Saarela et al., 2005).

The carbohydrate composition of human milk is important as a nutritional source of lactose and for the presence of oligosaccharides. A softer stool consistency, more nonpathogenic fecal flora, and improved mineral absorption have each been attributed to small quantities of unabsorbed lactose. Human milk oligosaccharides are bioactive carbohydrate polymers (also including glycoproteins) that help protect the infant because their structure mimics specific bacterial antigen receptors and prevent bacterial attachment to the host mucosa. Some examples of human milk oligosaccharides (HMOs) include fucosylated glycans that specifically inhibit binding by *Haemophilus influenzae*, *Campylobacter jejuni*, and some viral agents (Morrow et al., 2005). HMOs are also prebiotics that stimulate the growth of nonpathogenic bifidus bacteria.

The concentrations of calcium and phosphorus in human milk are significantly lower than in other milks; calcium and phosphorus are present in more bioavailable forms bound to digestible proteins and in complexed and ionized states (Neville and Watters, 1983). Thus the bone mineral content of breastfed infants is similar to that of infants fed formula (Venkataraman et al., 1992). The concentrations of copper and zinc, despite their decline throughout lactation, appear adequate to meet the infant's nutritional needs (Lonnerdal and Hernell, 1994). The concentration of iron, however, does not meet the term infant's needs beyond 4 to 6 months, so beginning at about 6 months, either an oral iron supplement or iron-containing complementary feedings are indicated to prevent subsequent iron-deficiency anemia; preterm and low birth weight infants should receive iron supplementation from birth (Greer and Suttie, 1988; Baker et al., 2010; Qasem et al., 2015).

The content of vitamin K in human milk in comparison with fortified formulas is very low, and a single injection of vitamin K should be given at birth to all infants to prevent vitamin K–deficiency bleeding, a rare condition for which breastfed infants are at greatest risk (Greer and Suttie, 1988; Shearer, 2009). The breastfed baby is particularly at risk because of the low vitamin K content of human milk and its association with the development of an intestinal microflora that makes less vitamin K. The content of vitamin D in human milk is dependent on maternal vitamin D status. However, many women have insufficient vitamin D stores, and vitamin D deficiency leading to rickets has been reported in breastfed infants, especially those with dark skin pigmentation and/or minimal exposure to sunlight (Weisberg et al., 2004). Oral vitamin D supplementation is indicated and can be accomplished either by giving the infant 400 international units (IU) daily or by advising the breastfeeding mother to take 6400 IU daily herself (Wagner and Greer, 2008; Hollis et al., 2015).

Nutritional Implications for the Premature Infant

Maternal breast milk is the preferred enteral feeding for premature infants, although its nutritional adequacy may be limited for several reasons (Henderson et al., 2007). The protein content of milk from mothers delivering prematurely is greater than that of milk from mothers delivering at term but never meets the needs of smaller and more immature preterm infants (Polberger and Raiha, 1995). Fat is the most variable nutrient in human milk, and its content differs throughout the day, from mother to mother, within a single milk expression, and during lactation (Neville et al., 1984). Further, since human milk is not homogenized, the fat content separates from the body of milk during standing and may be lost

with multiple milk transfers and tube feedings (Greer et al., 1984; Schanler, 1988). Gastrointestinal advantages of human milk as compared with preterm formula include faster gastric emptying, less feeding intolerance, and fewer days to full enteral feeds (Schanler et al., 1999; Tudehope, 2013; Assad et al., 2016). However, the concentrations of protein, sodium, and zinc decline throughout lactation, and the nutrient needs of the premature infant remain higher than those of term infants until after term postmenstrual age. Therefore in contrast to the term infant, this physiologic decline in milk protein and micronutrient content precedes any reduction in the premature infant's needs. For the very low birth weight (VLBW; <1500 g) infant, the feeding of unfortified human milk results both in protein insufficiency, manifest by declines in growth rates and lowered biochemical indicators (blood urea nitrogen [BUN] and serum prealbumin concentrations), and inadequate bone health, marked by declines in serum phosphorus concentration and increases in alkaline phosphatase activity, as compared with feeding of preterm formula (Rowe et al., 1979; Cooper et al., 1984; Kuschel and Harding, 2004).

Thus VLBW infants should receive human milk fortifier, a multinutrient supplement designed to meet their nutritional needs and prevent clinical deficiency diseases and growth failure. Meta-analysis comparing feeding of fortified (versus unfortified) human milk shows an increase in short-term weight, length, and head circumference growth without adverse effects (Kuschel and Harding, 2004). In addition, bone density, nitrogen balance, and BUN values are all increased with fortified human milk versus unfortified milk (Quigley and McGuire, 2014). Fortifier adds not only protein, calcium, phosphorus, and calories but also other micronutrients (Table 67.4). A new class of fortifiers derived from pasteurized donor human milk has been developed (Sullivan et al., 2010). The use of an exclusive human milk diet, made with human milk–based fortifier instead of bovine milk–based human milk fortifier, has been shown to result in lower rates of necrotizing enterocolitis (NEC) (Sullivan et al., 2010).

Human milk fortifier is usually added once the premature infant is tolerating tube feeding, and its use is continued until the infant has achieved all oral feedings, a weight of 1800 g, or is near to discharge from the hospital (Tudehope, 2013; Tudehope et al., 2013; Underwood, 2013). Evidence regarding postdischarge multinutrient fortification of breast milk is limited, and hence metaanalysis does not provide convincing guidance (Young et al., 2013). However, the infant will likely benefit from an individualized plan that includes supplementation or fortification, maternal lactation support, and monitoring to achieve a weight gain of more than 20 g/day until “catch up” to growth for corrected age has been achieved, linear growth of 0.5 cm/week, and an alkaline phosphatase level less than 450 IU/L (Groh-Wargo and Thompson, 2014). Usually the enriched diet is maintained for 3 to 6 months, but excessive growth (i.e., crossing more than two channels upward) should be avoided.

Host Defense: Prevention of Infections

Bioactive factors such as sIgA, lactoferrin, lysozyme, oligosaccharides, growth factors, and cellular components augment the infant's active host defenses (Table 67.5; Ballard and Morrow, 2013). Infants also receive specific passive immunity via the enteromammary immune system in which the mother produces sIgA antibody in response to foreign antigens, and specific antibodies are then elaborated at mucosal surfaces and in her breast milk (Kleinman and Walker, 1979).

TABLE 67.4 Nutrient Composition of Preterm Human Milk With and Without Fortifier

| | Preterm Human Milk (1 Week) | Mature Preterm Human Milk (1 Month) | Mature Preterm Human Milk Plus Human Milk Fortifier ^a |
|--------------------------------|-----------------------------|-------------------------------------|--|
| Volume (mL) | 100 | 100 | 100 |
| Energy (kcal) | 67 | 69 | 83 |
| Protein (g) | 2.4 | 1.5 | 2.5–2.6 |
| Whey/casein (%) | 70/30 | 70/30 | 70/30 |
| Fat (g) | 3.8 | 3.6 | 4.0–4.6 |
| Medium-chain triglycerides (%) | 2 | 2 | 11–17 |
| Carbohydrate (g) | 6.1 | 6.7 | 7.1–8.5 |
| Lactose (%) | 100 | 100 | 80–85 |
| Calcium (mg) | 25 | 29 | 119–146 |
| Phosphorus (mg) | 14 | 9.3 | 59–76 |
| Magnesium (mg) | 3.1 | 2.4 | 3.4–9.4 |
| Sodium (mEq, mmol) | 2.2 | 0.9 | 1.6 |
| Potassium (mEq, mmol) | 1.8 | 1.3 | 2–2.9 |
| Chloride (mEq, mmol) | 2.6 | 1.5 | 1.9–2.6 |
| Zinc (μg) | 500 | 215 | 935–1215 |
| Copper (μg) | 80 | 51 | 95–221 |
| Vitamin A (IU) | 560 | 227 | 847–1177 |
| Vitamin D (IU) | 4 | 1.2 | 122–151 |
| Vitamin E (mg) | 1.0 | 0.3 | 3.5–4.9 |

^aEnfamil human milk fortifier (Mead Johnson Nutritionals, Evansville, Indiana) and Similac human milk fortifier (Ross Laboratories, Columbus, Ohio) are powdered formulations that use bovine protein (based on addition of four packets to 100 mL mature preterm human milk). Liquid bovine milk protein–based fortifiers (Enfamil human milk fortifier acidified liquid and Similac human milk fortifier concentrated liquid) and liquid human milk–based fortifiers are also available (Prolacta+ H²MF[®] all-liquid milk fortifier [<http://www.prolacta.com/>]). Liquid fortifiers displace and hence reduce part of the volume of human milk that the infant receives. IU, International unit; Kcal, kilocalorie; mEq, milliequivalent.

In both developing and developed countries, there is a reduction in all-cause infection-related mortality attributable to breastfeeding, with a clear “dose response.” The dose response has been categorized as exclusively, predominantly, partially, or never breastfed. The relative risk of death due to all infectious causes is significantly greater in infants aged 0 to 5 months who were never breastfed

(relative risk [RR] 8.66) or who were partially breastfed (RR 4.56) and even who were predominantly but not exclusively breastfed (RR 1.7), each in comparison with exclusively breastfed infants aged 0 to 5 months. Children aged 6 to 23 months who were never breastfed, as compared with ever breastfed, had a 2.1 times higher risk of death (Sankar et al., 2015). In developing countries the incidence, prevalence, and mortality because of diarrheal illnesses are significantly decreased by breastfeeding. When compared with exclusive breastfeeding, mortality caused by diarrhea was higher among infants who were never breastfed (RR 10.52), partially breastfed (RR 4.62), or predominantly breastfed (RR 2.28) (Lamberti et al., 2011). These data demonstrate the “dose dependent” benefit of breast milk for prevention of death caused by diarrheal illness. Never breastfed infants aged 0 to 11 months, as compared with those who were predominantly breastfed, were also at greater risk of death from diarrhea illness (RR 11.73) (Lamberti et al., 2011). Even when only infants in the developed world are considered, the risk of nonspecific gastrointestinal disease is lower among infants aged 0 to 11 months who were ever breastfed as compared with those who were never breastfed (Ip et al., 2007). Exclusive breastfeeding for the first 6 months of life reduces the risk of otitis media in children younger than 2 years, and both longer duration and any versus no breastfeeding are protective (Bowatte et al., 2015); this benefit may extend through age 6 years (Li et al., 2014). Worldwide, the risk of acute lower respiratory tract infection (LRTI) caused by respiratory syncytial virus was increased by not breastfeeding (Shi et al., 2015); the risk of death because of pneumonia was higher for both never versus exclusively breastfed infants aged 0 to 5 months and for never versus ever breastfed children aged 6 to 23 months (Lamberti et al., 2013). In developed countries, after adjustment for day care, smoke exposure, and socioeconomic status, the risk of hospitalization because of LRTI was significantly lower for infants exclusively breastfed for 4 months versus those receiving no breast milk (Ip et al., 2007; Table 67.6).

Clinical studies throughout the world and over several decades have also suggested a decrease in the rates of morbidities in premature infants fed human milk (Narayanan et al., 1980; Hylander et al., 1998; El-Mohandes et al., 1998; Ronnestad et al., 2005). Pasteurized donor milk, rather than preterm formula, is now recommended for infants whose mothers are unable to provide full volumes of breast milk for their premature infant (Arslanoglu et al., 2013; Quigley and McGuire, 2014; AAP, 2015). Methodological issues, including differing definitions of “human milk” (mother’s own vs donor, frozen vs fresh, mixed with formula) and of human milk intake volume (mL/kg per day vs daily percentage of enteral or all intake) create difficulties in the interpretation of results, yet data from studies that quantified human milk intakes suggest that the protective effect is (1) optimized by an exclusive human milk diet and (2) likely dose dependent.

Premature infants who receive their own mother’s milk have a significantly lower risk of NEC after adjustment for gestational age, and metaanalysis confirms the magnitude of these results (Ip et al., 2007; Sisk et al., 2007; Meinen-Derr et al., 2009). Donor human milk is also protective against NEC in premature infants when compared with formula (see later) (Arslanoglu et al., 2013; Quigley and McGuire, 2014; Kantorowska et al., 2016). The risk of late-onset sepsis is likely reduced by human milk feeding (Schanler et al., 1999; Furman et al., 2003; Ronnestad et al., 2005; Cossey et al., 2013; Pammi and Weisman, 2015). NICU length of stay is shorter for human milk–fed infants: a direct relationship between lower risk of morbidity and dose of human milk (19% lower risk

TABLE 67.5 Selected Bioactive Factors in Human Milk**Immunoglobulins**

| | |
|-------------------------------------|---|
| Secretory IgA | Specific antigen-targeted antiinfectives |
| IgG | Antimicrobial |
| IgM | Complement activation |
| Lactoferrin | Immunomodulation, iron chelation, antimicrobial action, antiadhesive, trophic for intestinal growth |
| Lactadherin | Antiviral and antiinflammatory |
| Lysozyme | Bacterial lysis, immunomodulation |
| κ -Casein | Antiadhesive, bacterial flora |
| Oligosaccharides | Stimulate colonization by beneficial organisms |
| Gangliosides and glycosaminoglycans | Prevent infections |
| Cytokines ^a | Antiinflammatory, proinflammatory, epithelial barrier function, recruit neutrophils |
| Macrophages | Antiinfectious and activate T cells |

Growth Factors

| | |
|--|--|
| Epidermal growth factor | Luminal surveillance, repair of intestine |
| Transforming growth factor | Promotes epithelial cell growth (transforming growth factor- α) Suppresses lymphocyte function (transforming growth factor- β) |
| Nerve growth factor | Promotes growth of neurons |
| Vascular endothelial growth factor | Promotes angiogenesis and tissue repair |
| Insulin-like growth factor | Promotes growth |
| Macrophage migratory inhibitory factor | Prevents macrophage movement |

Hormones

| | |
|--------------|---|
| Adiponectin | Reduction of infant BMI, antiinflammatory |
| Leptin | Regulation of infant BMI and appetite |
| Calcitonin | Promotes development of enteric neurons |
| Somatostatin | Regulates growth of gastric epithelium |

Enzymes

| | |
|--|---|
| Platelet-activating factor acetylhydrolase | Blocks action of platelet-activating factor |
| Glutathione peroxidase | Prevents lipid oxidation |
| Nucleotides | Enhance antibody responses, bacterial flora |
| Vitamin A, E, C | Antioxidants |
| Glutamine (amino acid) | Intestinal cell fuel, immune responses |
| Lipids | Antiinfective properties |
| Mucins 1 and 4 | Block infectious agents |

^aIncludes interleukins 6, 7, 8, and 10, tumor necrosis factor- α , transforming growth factor- β , and interferon gamma.

BMI, Body mass index.

Modified from Schanler RS, Krebs N, and Mass S, eds. *AAP/ACOG Breastfeeding Handbook for Physicians*. Elk Grove, IL: American Academy of Pediatrics; 2013:77 and Ballard O, Morrow AL. Human milk composition: nutrients and bioactive factors. *Pediatr Clin North Am*. 2013;60:49–74.

for each additional 10 mL of human milk/kg/day) and significantly lower NICU costs has been documented, and exclusive human milk feeding, as compared with all other diets, was associated with reduced risk of NEC ($P < .011$), fewer days to full feeds ($P < .001$), and lower hospitalization cost (savings up to \$106,968 per

infant) (Patel et al., 2013; Assad et al., 2016). The rates of both any-stage and severe retinopathy of prematurity are decreased by human milk feeding, with a dose response noted (Zhou et al., 2015). Exclusive human milk feeding is also associated with reduced risk of bronchopulmonary dysplasia (Spiegler et al., 2016).

TABLE 67.6 Benefits of Breastfeeding for Infants and Mothers

| Condition | Comparison | Odds Ratio | 95% Confidence Interval |
|--|--|------------|-------------------------|
| Maternal Benefits | | | |
| Breast cancer | All for each additional 12 months of lactation | 0.74 | 0.69–0.79 |
| Ovarian cancer | | 0.63 | 0.56–0.71 |

Chronic Conditions of Childhood

Data from epidemiologic studies suggest that certain chronic disorders have a lower incidence in children who were breastfed as infants; however, causal relationships between breastfeeding and the health outcomes of interest are difficult to infer because of the nature of the studies that can be performed (Table 67.6). Among

these are inflammatory bowel disorders and type 1 diabetes, each with limited or conflicting evidence for a protective effect (Klement et al., 2004; Patelarou et al., 2012; Silano et al., 2016). A 19% reduced risk of childhood leukemia has been associated with breastfeeding for 6 months or more (Amitay and Keinan-Boker, 2015). Dental caries are reduced by longer duration of breastfeeding, although breastfeeding beyond 12 months may actually increase

risk (Tham et al., 2015). Data are conflicting regarding allergic disease, but metaanalysis shows reduced risk of asthma at age 5 years to age 18 years for ever versus never breastfeeding and for more versus less breastfeeding, with no impact of stratification by family atopy (Lodge et al., 2015). Reduced risk of eczema before age 2 years, but not after, was associated with exclusive breastfeeding for 3 to 4 months (Lodge et al., 2015). Breastfeeding does not specifically reduce the risk of food allergies, although it appears to reduce the risk of generalized allergic disease before age 5 years (Lodge et al., 2015).

There appears to be an inverse relationship between exclusivity and duration of breastfeeding and the risk of obesity and overweight in childhood and adulthood (metaanalyses showing pooled odds ratio (OR) of 0.74; 95% confidence interval (CI) 0.70–0.78) (Ip et al., 2007; Horta et al., 2015b). This association is stronger for studies assessing exclusive breastfeeding and for those reporting children as compared with adults and is weaker for studies with large numbers of participants (>1500) and for those that adjusted the data for relevant confounders, including maternal BMI, birth weight for gestational age, and socioeconomic factors. Although it is difficult to eliminate the possibility of residual confounding by unmeasured lifestyle factors, high-quality studies from high-, medium-, and low-income settings show a 13% reduction in the risk of obesity with breastfeeding (summary OR 0.87; 95% CI 0.76–0.99) (Ip et al., 2007; Horta et al., 2015b). Biologically plausible mechanisms for this effect include more optimal self-regulation of energy intake when feeding at the breast (Li et al., 2012), higher protein/energy intake among formula-fed than breastfed infants leading to neonatal obesity and hence childhood obesity (Heinig et al., 1993; Rolland-Cachera et al., 1995; Stettler et al., 2002), differences in release of insulin and other gut and pancreatic hormones in formula-fed versus breastfed infants that may alter fat deposition patterns (Lucas et al., 1980), and reduced risk of type 2 diabetes mellitus with breastfeeding (Horta et al., 2015b). Additionally, hormones in breast milk, including leptin, adiponectin, and ghrelin, appear to regulate appetite, growth, fat deposition, and energy balance, which may explain differences in early body composition and later BMI between breastfed and formula-fed infants (Savino et al., 2009; Kon et al., 2014). Neither blood pressure nor cholesterol levels in later life appear to be impacted by breastfeeding (Owen et al., 2008; Horta et al., 2015b).

Neurobehavioral Aspects

Whether an improvement in cognitive ability is attributable to breastfeeding and/or human milk has been difficult to determine. Disagreement has remained even when (1) results are adjusted for the key confounders of maternal intelligence, education, and socioeconomic class, and (2) only studies meeting rigorous standards are included (Ip et al., 2007). However, metaanalysis using strict study criteria found that breastfeeding was positively associated with an average gain of 3.44 points (95% CI 2.30–4.58 points) on intelligence testing in childhood and adolescence for breastfed individuals. When only the highest-quality studies ($n = 4$ with sample size >500, breastfeeding recall time <3 years, controlled for maternal intelligence) were examined, the gain on intelligence testing was still significant (1.76 points; 95% CI 0.25–3.26 points) (Horta et al., 2015a).

Significantly improved neurodevelopment among extremely low birth weight infants as measured by the Bayley Scales of Infant Development II at age 18 to 22 months and age 30 months has

been correlated with the receipt of fortified human milk during hospitalization. The magnitude of the effect at 18 to 22 months was greatest in the highest quintile (>80%), who averaged 110 mL/kg per day of human milk, and at 30 months the effect persisted such that for every 10 mL/kg per day increase in human milk, the Mental Developmental Index increased by 0.59 points, the Psychomotor Developmental Index increased by 0.56 points, and the total behavior percentile score increased by 0.99 points (Vohr et al., 2006, 2007).

Mother–infant bonding is also enhanced during breastfeeding (Feldman et al., 2007; Galbally et al., 2011). The likely biologic basis for this universal observation is oxytocin, which causes the milk ejection reflex during nursing, and serves as a central neurotransmitter that directly affects maternal nurturing behaviors, mother–infant social interaction, gaze, vocalizations, and affectionate touch (Britton et al., 2006).

Infant and Childhood Mortality

The risk of all-cause death worldwide was higher among children aged 0 to 5 months for those who were not breastfed (RR 14.4), partially breastfed (RR 4.8), and predominantly breastfed (RR 1.5) as compared with those who were exclusively breastfed (Sankar et al., 2015). Children aged 6 to 23 months who were not breastfed had higher all-cause mortality than those who continued breastfeeding; mortality decreased with exclusivity and duration of breastfeeding, but any breastfeeding was protective (Sankar et al., 2015). Breastfeeding also appears protective against sudden infant death syndrome (SIDS) (Hauck et al., 2011). On metaanalysis the risk of SIDS was lowered for exclusively breastfed infants and for infants with any breastfeeding (Hauck et al., 2011). Although a direct mechanism is not known, the effect is strong and dose dependent and does not appear only as a marker for confounders such as passive smoking or demographic factors.

Maternal Benefits

There are numerous benefits of breastfeeding for the mother (Table 67.6). Lactation has a beneficial effect on lipid and glucose metabolism and is associated with significant reduction in the risk of type 2 diabetes and cardiovascular morbidities (Schwarz et al., 2009; Aune et al., 2014; Chowdhury et al., 2015). Multiple studies have documented a significantly decreased incidence of premenopausal breast and ovarian cancer in women who have breastfed (Collaborative Group on Hormonal Factors in Breast Cancer, 2002; Chowdhury et al., 2015). Neither rapid postpartum weight loss nor changes in bone mineral density are attributable to breastfeeding; however, the risk of postpartum hemorrhage may be decreased by breastfeeding combined with skin-to-skin care, although additional study is needed (Chowdhury et al., 2015; Abedi et al., 2016). Postpartum depression both predicts and is predicted by cessation of breastfeeding; it is not known whether breastfeeding can directly reduce postpartum depression (Dias and Figueiredo, 2015). Exclusive breastfeeding delays resumption of normal ovarian cycles and the return of fertility, probably because of an elevated prolactin level (McNeilly, 1993). The lactational amenorrhea method, defined by full breastfeeding (round-the-clock), no resumption of menses, and infant age less than 6 months, is a highly effective global contraceptive program with efficacy rates of 98.5%–100% (Peterson et al., 2000; WHPO, 2017). Breastfeeding can therefore contribute to child spacing, which additionally improves maternal and child health.

Societal Impact of Breastfeeding

From a national economic perspective, it has been estimated that if all infants enrolled in the WIC program were breastfed exclusively for the first 6 months of life, food package costs would be reduced by 18%, realizing approximately \$1.2 million of savings (Institute of Medicine, 2010; Hartmann et al., 2012; US Department of Agriculture, Food and Nutrition Service, 2015). Additional savings can accrue from a reduction in household expenditure on formula and healthcare costs, with less parental work absence because of the decreased rates of illness experienced by breastfed infants; costs significantly drop with every additional month of breastfeeding and each month delay in return to work after 3 months (Cattaneo et al., 2006). Cost analyses estimating the burden of suboptimal breastfeeding for maternal health alone predicted a \$733.7 million direct loss to society; similar analyses showed that if 80% of US families exclusively breastfed for 6 months, \$10.5 billion would be saved and 741 infant deaths would be prevented (Bartick and Reinhold, 2010; Bartick et al., 2013). Thus extraordinary societal and economic incentives support attainment of full breastfeeding for each infant–mother dyad.

Contraindications to Breastfeeding

Few true contraindications to breastfeeding exist (Box 67.2; AAP/ACOG, 2012; CDC, 2016). Mothers with fever or other minor illness should be permitted to breastfeed, since the infant has already been exposed to the infectious agent and will be able to benefit from the mother's developing immunity if breastfeeding can continue. Few maternal medications contraindicate breastfeeding, and alternative choices are available in most cases; the National Institutes of Health US National Library of Medicine Drugs and Lactation Database (<https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>) is the optimal resource and should be consulted (US National Library of Medicine, 2015). Mothers who have undergone breast reduction or breast implant surgery can breastfeed but should work closely with a lactation specialist because milk supply may be negatively impacted if ducts or nerves were severed during surgery.

Anatomy and Physiology of Lactation

Breast milk is produced by the mammary alveolar cells of the breast after childbirth. The mammary gland is a highly evolved skin gland, and its rudiments are first seen during the sixth week in utero. Mammogenesis, or breast development, begins during puberty with increased breast size due mainly to estrogen and lobuloalveolar development facilitated predominantly by progesterone. During pregnancy, with the support of these hormones and others, including prolactin and placental lactogen, breast glandular tissue further differentiates, and the alveolar epithelium proliferates and then becomes secretory. Research using ultrasound technology (Fig. 67.1) shows that the milk ducts branch close to the nipple, that their number is lower and more variable than previously believed, that most glandular tissue is close to the nipple, and that the “lactiferous sinuses,” which were thought to store milk, do not exist (Ramsay et al., 2005). These findings have implications for hand expression of breast milk, since inadvertent pressure on the breast close to the nipple may actually inhibit milk flow, as well as for breastfeeding after breast augmentation or reduction surgery, since major nerves and milk ducts may have been unintentionally severed or damaged during surgery, with risk of reduced milk supply.

• BOX 67.2 Contraindications to Breastfeeding

Maternal

- Untreated active maternal military tuberculosis: Refrain from breastfeeding or infant contact until treated and no longer contagious, approximately 2 weeks.
- Active herpetic lesions on the breast: Refrain from breastfeeding until active lesions on breast and nipple have resolved. Vaginal herpes is not a contraindication.
- Active varicella (chickenpox) lesions on the breast: Express milk until lesions are crusted over; administer varicella immunoglobulin to infant.
- Active human immunodeficiency virus (HIV) infection: Active HIV infection is not an absolute contraindication in developing countries.^a
- Active human T-lymphotrophic virus (types 1 and 2) infection: Use of illicit drugs is an absolute contraindication.^b
- Drug-free methadone-maintained women can breastfeed.
- Cancer chemotherapy or radiation treatment: For the duration of treatment, seek consultation for diagnostic studies using radiation to determine duration for which expressed milk must be discarded.
- Acute maternal illness with swine flu (H1N1 flu):^c
 - If the mother is ill, her infant should ideally be fed the mother's expressed breast milk by someone who is not ill.

Infant

- Galactosemia: Lactose cannot be ingested and is the carbohydrate of breast milk.
- Other inborn errors of metabolism require consultation regarding the specific metabolic defect(s).

^a“Since 2010, the World Health Organization has recommended that mothers who are HIV-infected take ARVs [anti-retroviral medications] and exclusively breastfeed their babies for 6 months, then introduce appropriate complementary foods and continue breastfeeding up to the child's first birthday.... Even when ARVs are not available, mothers should be counseled to exclusively breastfeed for 6 months and continue breastfeeding thereafter unless environmental and social circumstances are safe for, and supportive of, feeding with infant formula.” World Health Organization recommendation available at <http://www.who.int/mediacentre/factsheets/fs342/en/>.

^bThe American Academy of Obstetricians and Gynecologists (Committee opinion no. 637: Marijuana use during pregnancy and lactation. American College of Obstetricians and Gynecologists. Obstet Gynecol 2015;126:234–8) and the American Academy of Pediatrics (<http://pediatrics.aapublications.org/content/135/3/584>) strongly discourage cannabis use during lactation; the chapter authors acknowledge evidence is limited and individualized care is important.

Data from Kimberlin DW, Brady MT, Jackson MA, Long SS. Red book: 2015 report of the Committee on Infectious Diseases. Elk Grove, IL: American Academy of Pediatrics, 2015; Division of Nutrition, Physical Activity, and Obesity, National Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control and Prevention. Diseases and Conditions. When should a mother avoid breastfeeding? <http://www.cdc.gov/breastfeeding/disease>; 2016; and Hill M, Reed K. Pregnancy, breast-feeding, and marijuana: a review article. Obstet Gynecol Surv. 2013;68:710–718.

Lactogenesis begins by midpregnancy, although actual milk secretion does not occur at this time because of high circulating levels of progesterone (and probably estrogen). During pregnancy, secretory differentiation of the mammary epithelial cells into lactocytes that have the ability to produce milk components occurs: this is known as *lactogenesis I*. At the end of gestation the alveoli are filled with proteins, including sIgA, and leukocytes and desquamated cells: this glandular fluid is colostrum. Lactogenesis II, or secretory activation of the lactocytes (also known as *the milk coming in*), usually occurs between day 2 and day 8. This phase, defined by the copious onset of milk secretion, is triggered by birth and the drop in progesterone level associated with removal of the placenta. Adequate circulating prolactin and cortisol levels are required, and other hormones, including insulin and thyroid hormone, likely play a supporting role. During this time daily milk volume increases from about 50 to

• **Fig. 67.1** Anatomy of the breast. (From Medela AG. Old vs new anatomy. (Available at <http://www.medelabreastfeedingus.com/for-professionals/cbe-information/106/breast-anatomy-research>.) 1-Ducts branch closer to nipple, 2-The conventionally described lactiferous sinuses do not exist, 3-Glandular tissue is found closer to the nipple, 4-Subcutaneous fat is minimal at the base of the nipple.

500 mL, and transitional milk is produced, a descriptor for milk that is literally transitioning in composition from colostrum to mature milk (Neville, 1999; Neville et al., 2001; Pang and Hartman, 2007).

The control of lactogenesis is completely hormonal. Evidence suggests that milk removal or infant suckling is not needed for the programmed changes of lactogenesis, although milk removal may improve the efficiency of early milk secretion (Neville et al., 2001). Delayed lactogenesis II has been associated with placental retention (failure of progesterone level to decline postpartum), hypothyroidism, cesarean delivery, and premature delivery; there are also associations with factors related to glucose metabolism, including maternal insulin-dependent diabetes, elevated maternal BMI, and higher infant birth weight (Nommsen-Rivers et al., 2012).

If the mother begins to feed her infant at the breast (or to express milk from the breast), then the next phase of lactation, called *galactopoiesis* or *maintenance of milk secretion*, starts at approximately day 9 postpartum and continues until weaning and involution of the breast. The control of galactopoiesis is both endocrine and autocrine. Prolactin and cortisol are necessary for milk production: prolactin binds to epithelial cell receptors and is responsible for activating the milk protein genes for α -lactalbumin and casein. Milk synthesis remains near 700 to 800 mL/day throughout lactation, but the actual volume of milk is dependent on milk removal. With incomplete emptying of the breast because of infrequent or inefficient infant suckling, milk synthesis is adjusted downward because of a locally produced whey protein called *feedback inhibitor of lactation* (FIL). FIL appears to act on alveolar cell receptors to decrease their sensitivity to prolactin and therefore to decrease milk production. The cellular mechanisms for milk synthesis and secretion are described elsewhere (Neville, 1999; Neville et al., 2001).

Milk that was accumulated in the alveoli cannot flow passively into the ducts. Actual milk ejection, or galactokinesis, is dependent on the hormone oxytocin, which is produced in the posterior pituitary. Oxytocin secretion is stimulated by infant suckling and other sensory inputs that mimic the infant such as cry, sight, smell, and touch. Stretch receptors in the canalicular ductal system are

• **Fig. 67.2** The milk secreting unit: the terminal duct lobular unit. a, Alveoli, d, ductule, PC, plasma cells. (From Neville MC. Milk secretion: an overview. Available at http://www.health-e-learning.com/articles/Neville_MILK_SECRETION_2008.pdf.)

activated, and afferent nerve endings send a signal to the central nervous system. The alveolar lactocytes are wrapped with myoepithelial cells that lack innervation but have oxytocin receptors (Fig. 67.2). In the presence of oxytocin, they squeeze milk into the ducts, leading to milk ejection. Prolactin originates in the anterior pituitary, and although secretion is also stimulated by suckling, prolactin production is not inhibited by pain and stress like that of oxytocin, and the milk ejection reflex, or “let down,” does not directly depend on it.

During weaning or extended periods of infrequent suckling at the breast, levels of prolactin drift downward. The tight junctions between alveolar lactocytes appear to open and allow passage of

electrolytes, including sodium and chloride. Elevated breast milk sodium level is associated with several clinical situations, including involution and remodeling of the mammary gland, which occurs with cessation of milk secretion (Lawrence et al., 2016).

Management of Breastfeeding

The management of lactation begins before pregnancy (AAP/ACOG, 2012; ACOG, *Optimizing Support for Breastfeeding*, 2016). Formal prenatal breastfeeding education (BFHI step 3), in addition to personalized information offered during prenatal visits, positively impacts exclusive breastfeeding and breastfeeding at 6 months (Academy of Breastfeeding Medicine [ABM] Clinical Protocol 19, Breastfeeding Promotion in the Prenatal Setting, <http://www.bfmed.org/Resources/Protocols.aspx>; Lawrence et al., 2016). Ideally breastfeeding education, and the function of the mammary glands, should be taught in secondary school and continued throughout the reproductive life cycle. In support of this approach, maternal prenatal intention to breastfeed appears to be the best predictor of breastfeeding initiation and duration (Donath et al., 2003; Stuebe and Bonuck, 2011). Obstetric providers should initiate the discussion of breastfeeding as an evidence-based choice and should encourage and support mothers in setting their own breastfeeding goals.

Hospital Care

Hospital management of delivery room and postpartum mother–infant routines (Box 67.1) has also been shown to impact rates of breastfeeding (Kramer et al., 2001; Philipp et al., 2001; DiGirolamo et al., 2008; Rosenberg et al., 2008; AAP, *Breastfeeding and the use of Human Milk*, 2012; Moore et al., 2012; Sinha et al., 2015; Yotebieng et al., 2015; Olaiya et al., 2016). As summarized by the ABM Clinical Protocol 5, Peripartum Care, and Clinical Protocol 7, Model Hospital Policy (<http://www.bfmed.org/Resources/Protocols.aspx>), written hospital guidelines should promote and support breastfeeding for each mother–infant dyad per recommendations of the American Academy of Pediatrics and WHO, maximize each mother’s ability to meet her own breastfeeding goals, and maximize each infant’s opportunity to receive full feeds of breast milk (BFHI step 1) (AAP, *Breastfeeding and the use of Human Milk*, 2012; Feldman-Winter et al., 2012; Sample Hospital Breastfeeding Policy for Newborns, 2016). The BFHI 10 steps serve as a useful and evidence-based guide to hospital policy (Box 67.1). Each evidence-based step may require changes in entrenched hospital routines that are not conducive to breastfeeding. For example, mothers should be encouraged to put the infant to breastfeed within the first hour after birth (BFHI step 4). Newborns that are placed skin-to-skin on the mother’s abdomen a few minutes after birth are able to initiate a “crawl” toward the breast and nipple, latch on, and begin sucking (<http://www.breastcrawl.org/video.shtml>). The necessary medical routines of infant identification, drying, warmth, assessment, and administration of prophylactic eye drops and vitamin K can be safely delayed until after the first breastfeeding for healthy infants (AAP, *Breastfeeding and the use of Human Milk*, 2012).

Initial Management

Normal healthy infants are able to latch on to the breast in the first hour after birth. The goals for the infant during the postpartum stay include (1) achievement of latch on to the breast within the

• BOX 67.3 Risk Factors for Lactation Failure or Difficulty

Maternal Factors

Maternal chronic illness (e.g., cystic fibrosis, diabetes type 1 or 2)

Anatomic

Prior breast surgery

Inverted nipples, nipple size mismatch with infant mouth

Tubular or variant breast shape (size per se is not a factor)

Obesity

History of breastfeeding difficulty

Perinatal complications (e.g., hemorrhage, hypertension/preeclampsia, shock, infection)

Cesarean delivery

Multiples (twins, triplets, etc.)

Mother–infant separation

Secondary—nipple trauma, nipple pain, engorgement

Infant Factors

Premature delivery <34 weeks

Late preterm delivery (34 to 36 weeks’ gestation)

Early term delivery at 37 weeks

Birth weight large or small for gestational age

No effective latch in the first 24 hours

Anatomic or congenital anomaly

Trisomy

Major congenital malformation

Micrognathia, Pierre Robin sequence

Cleft palate or lip

Macroglossia or ankyloglossia

Neurologic abnormality with hypotonia or hypertonia

Neonatal intensive care unit admission/perinatal complications (e.g., hypoxic–ischemic encephalopathy, pneumonia)

Sleepy infant for any cause

Mother–infant separation

Secondary—supplementation more than once in 24 hours, weight >7% below birth weight, excessive pacifier use

first few hours after birth, (2) ability to transfer milk (or colostrum) adequately at each feeding, (3) feeding at the breast 8 to 12 times per 24 hours as cued by infant hunger (rooting, fist sucking, alerting), (4) nursing at both breasts each feeding for up to 15 to 20 minutes per side or until there are signs of infant satiety (fewer sucking bursts, longer pauses, sleepiness), and (5) the mother feeling comfortable with the infant feeding at the breast. Maternal and infant risk factors for lactation difficulty (Box 67.3) should be identified within the first few hours after birth so that interventions to promote maternal and infant health and the breastfeeding process can be promptly initiated, and this assessment process should be ongoing throughout the hospital stay.

Latch On

“Good latch” is the cornerstone of successful breastfeeding because it permits adequate milk transfer to the infant and prevents nipple pain for the mother. Brief videos are available that demonstrate how to assist a mother achieve latch (*Basics of Breastfeeding*). Nursing at the breast is fundamentally different from bottlefeeding in that the infant extracts the milk from behind the nipple while nursing rather than sucking on the nipple to elicit flow. There are several ways to hold an infant to breastfeed, but to achieve good latch, the mother and infant should be tummy-to-tummy, regardless

of the holding position, with the infant facing the mother's body (AAP/ACOG, 2012). The mother can hold her breast well behind the areola using a "C hold" with four fingers under the nipple and the thumb above. She then strokes the infant's mid upper lip with her nipple, and once rooting is elicited and the infant opens its mouth, she can promptly bring the infant in so it takes in the breast, including the areola, not just the nipple. The mother's nipple is protected since it is well back in the infant's mouth, and the infant's jaw massages milk from behind the areola. The infant's nose and chin will contact the mother's skin, and the mother should experience a tugging sensation without pain as the infant suckles with this deep latch. Many women acknowledge that breastfeeding is initially painful because of challenges with establishing good latch and because of the uterine contractions elicited by oxytocin during "let down," but if breast or nipple pain persists, prompt breastfeeding assistance is needed.

The First 2 Weeks to 2 Months

Each hospital should establish breastfeeding support groups or work with organized community support groups so that families have a resource on leaving the hospital (BFHI step 10). All breastfed infants should be seen by a knowledgeable healthcare professional at 3 to 5 days of age to recognize and to avoid potential problems of dehydration and severe jaundice (AAP, 2015).

The nursing history differs from infant to infant and over any 24-hour period, so although nursing 8 to 12 times per day is the average, some infants will "cluster feed," nursing more frequently for short periods. Without anticipatory guidance, new mothers may compare their infants with bottlefed infants and misinterpret the normal frequency of breastfeeding to mean that they have insufficient milk. As infants get older, they nurse more efficiently, and the frequency and duration of feedings decrease. New parents may expect their baby to cry when it is hungry and need guidance that crying is a late sign of hunger and can result in an infant who is difficult to calm and latch. Earlier hunger signs include rooting, finger and fist sucking, and lip smacking. Pacifier use is associated with a reduction in the risk of SIDS. However, pacifiers should not be introduced to breastfeeding infants until breastfeeding is well established, at about 3 to 4 weeks of age, because frequent use of a pacifier can conceal hunger cues, and the offering of artificial nipples may interfere with latch, both of which can adversely impact maternal milk supply (Hauck et al., 2011; Task Force on Sudden Infant Death Syndrome, 2011).

Once lactogenesis stage II is completed (the "milk has come in"), an infant who did not lose excessive weight and who is nursing effectively should obtain enough milk to begin gaining weight, 15–30 g per day, by day 4 or 5. At this rate, most breastfed infants will exceed their birth weight by 10 to 14 days and gain 20–30 g per day for the first 2 months. A breastfed infant who weighs less than birth weight at 2 weeks requires evaluation and intervention. Anticipatory guidance should include information about growth spurts, in which infants are restless and breastfeed more often than usual for 2 to 3 days. These typically occur at approximately ages 10 days, 3 weeks, 6 weeks, 3 months, and every few months and may be exhausting for the mother. Since milk supply depends on infant demand, permitting the infant to breastfeed frequently is optimal. In addition, screening for maternal depression, which is associated with a decreased duration of breastfeeding, and for other maternal concerns, such as sore nipples, is critical (AAP/ACOG, 2012; Dias and Figueiredo, 2015).

Growth of the Breastfed Infant

The rate and pattern of weight gain of breastfed infants differs from that of infants fed formula, and several studies have concluded that the breastfed infant's growth should be considered normative (Butte et al., 1984b, 1990; Dewey et al., 1991, 1992). The WHO Multicentre Growth Reference Study was undertaken between 1997 and 2003 and gathered primary longitudinal growth data from about 8500 healthy and optimally breastfed children of differing ethnic, racial, and cultural backgrounds (Brazil, Ghana, India, Norway, Oman, and the United States). WHO subsequently published an international growth reference (<http://www.who.int/childgrowth/>) based on the growth of these healthy and fully breastfed infants that benchmarks growth and development from birth to age 5 years, replacing older references (de Onis et al., 2006). See the Centers for Disease Control and Prevention growth charts, which use the WHO standards (http://www.CDC.gov/growthcharts/who_charts.htm).

Clinicians are occasionally in doubt as to when and how to intervene if a breastfed infant is not gaining adequate weight (Powers, 2001). A newborn younger than 2 weeks must be evaluated if its weight is more than 10% below birth weight. A newborn who fails to regain birth weight by 2 weeks of age or is not gaining a minimum of 20 g per day should be evaluated. The infant with growth faltering, when the weight for age (or weight for length) is less than two standard deviations below the mean or weight for age crosses more than two percentile channels downward on the growth chart, should also be evaluated. Infant physical examination and assessments of milk supply, intake, appropriateness of complementary foods, maternal history and behaviors, and the home environment are all part of the evaluation. Test weighing with an electronic scale before and immediately after a feeding is one method of measuring milk intake (Meier et al., 1990). Pumping after a feeding is a method to assess residual milk. Causes of growth problems not specifically related to breastfeeding must be considered, for example, cystic fibrosis or cardiac disease in the infant or severe postpartum depression in the mother.

Tongue Tie

Tongue tie, or ankyloglossia, is a congenital disorder with a male predominance (3:1), found in 4%–16% of infants, in which there is a short lingual frenulum that may restrict tongue movement and impact function, including breastfeeding. Poor latch with maternal nipple pain and insufficient milk transfer may result, although less than half of infants with even moderate to severe tongue tie appear to be affected (Ngerncham et al., 2013). As described in ABM Clinical Protocol 11, Neonatal Ankyloglossia (<http://www.bfmed.org/Resources/Protocols.aspx>), standardized clinical tools to assess the degree of tongue tie and its impact on breastfeeding include the Hazelbaker assessment tool for lingual frenulum function (Amir et al., 2006). One-week prefrenotomy and postfrenotomy changes in sucking pattern and milk transfer were demonstrated on submental ultrasonography (Geddes et al., 2008); however, whether or not frenulotomy (division of the frenulum), frenulectomy (removal of the frenulum), or frenuloplasty (frenulotomy with stitches) clearly improves breastfeeding has been controversial. Systematic reviews including five randomized controlled studies, of which four used validated measures of latch as a primary outcome, concluded that frenotomy in selected infants appears to provide objective improvements in breastfeeding

measures, with subjective improvement in maternal pain (Brooks et al., 2014; Francis and Krishnaswami, 2015).

Breastfeeding the Late Preterm Infant

Late preterm infants (34–36 weeks' gestation) are at high risk of complications of insufficient breast milk intake, including dehydration, hypernatremia, severe jaundice, and poor weight gain, and their mothers are at high risk of lactation failure due to immature and ineffective infant sucking, as reviewed in ABM Clinical Protocol 10, Breastfeeding the Late Preterm Infant (<http://www.bfmed.org/Resources/Protocols.aspx>) (Raju, 2006; Meier et al., 2013). Within hours of birth the mother can be taught to hand express colostrum to feed the baby, and within 24 hours of birth she can express breast milk every 2 to 3 hours after breastfeeding using a hospital-grade electric pump. Infant interventions include waking the infant to feed and providing supplementation with or after each feeding at least every 2 to 3 hours with expressed colostrum or breast milk (mixed with formula if there is not yet enough breast milk). This “trio” of nursing at the breast, followed by supplementation (or simultaneous if a supplemental nursing system is used) and then maternal milk expression, forms “triple feeds,” a bridge to successful lactation for the at-risk mother–infant dyad. In this manner the mother's milk supply is not at risk or diminished because of ineffective or infrequent sucking, and the physiologically immature infant is guaranteed sufficient intake. A breastfeeding management plan should be established before discharge.

Breastfeeding the Very Low Birth Weight Premature Infant

Mothers of VLBW and premature infants face multiple barriers to breastfeeding, including potentially incomplete mammary gland growth and inadequate priming of the mammary epithelium, mother–infant separation, infant fragility, the need to maintain milk supply by milk expression for weeks to months, and fatigue and stress, which may inhibit lactation (Jones and Spencer, 2007). Mothers can be encouraged to begin milk expression shortly after delivery and maintain a pumping frequency of eight times per day to optimize and maintain milk production (Furman and Minich, 2002; Jones and Spencer, 2007). Milk volume on day 4 may be predictive of supply at 6 weeks (Hill et al., 1999); those who combine massage or hand expression (“hands-on pumping”) with use of a double electric breast pump can exceed term milk volumes and may increase the caloric density of their milk (Jones et al., 2001; Morton et al., 2009, 2012). Lactation counseling does not increase maternal stress and anxiety and can increase the number of mothers who initiate lactation and the volume of breast milk their infants receive (Sisk et al., 2006). Multifaceted approaches to lactation support, including education of staff and parents, skin-to-skin (kangaroo) care, supportive hospital policies, peer support groups with transportation assistance, access to breast pumps, and lactation consultant availability, have all been demonstrated to increase rates of breast milk provision for VLBW infants (Meier et al., 2004; Dereddy et al., 2015).

Maternal Breastfeeding Issues

Nipple Pain

Sore nipples and pain are the most common complaints of breastfeeding mothers in the immediate postpartum period. Early,

mild discomfort is common, but severe nipple pain, the presence of cracks or bruises, discomfort that continues throughout a feeding, or pain that is not reducing by the end of the first 2 weeks is not normal. The most common cause of nipple pain is difficulty with breastfeeding technique, specifically improper latch, and prompt skilled help is the primary intervention. Limited milk transfer occurs when the infant is attached incorrectly, resulting in poor infant weight gain and impaired milk production. Other potential causes of nipple pain include overzealous breast cleansing, use of preparations that irritate the skin, skin trauma leading to impetigo, *Candida* infection, and rarely dermatologic conditions. Treatment for nipple pain depends on the underlying cause. If severe trauma exists, it may be necessary either to express milk or use a nipple shield with guidance from a lactation specialist until the nipple has healed; other therapies are not evidence based (Dennis et al., 2014). Ultrathin nipple shields may also help the infant latch on to inverted, flat, or engorged nipples, may reduce rapid milk flow, may facilitate milk transfer for premature infants, and may support the transition back to the breast for bottlefed infants.

Engorgement and Blocked Ducts

Physiologic breast fullness occurs because of vascular congestion during lactogenesis II. Pathologic engorgement, in which the infant cannot initially remove milk, is the firm, diffuse, and painful overfilling and edema of breasts usually caused by rapid increase in milk volume or a skipped feeding. As described in ABM Clinical Protocol 20, Engorgement (<http://www.bfmed.org/Resources/Protocols.aspx>), the best treatments for engorgement are a warm shower and gentle hand massage to soften the areola and permit the infant to attach and frequent effective breastfeeding (or hand milk expression if the infant is not able to breastfeed) followed by cool packs for 5 minutes after each feeding. “Reverse pressure softening,” a simple technique in which gentle pressure pushes fluid backward and upward in the breast to reduce areolar edema and permit latch, may also be effective (Cotterman, 2011). Engorgement should not be confused with a plugged milk duct, which can result in a localized lump in one area of the breast, usually because of infrequent or ineffective feedings or local pressure because of constrictive clothing. Treatment includes warm packs, gentle massage from the painful area toward the nipple, frequent effective feedings using different infant positions to facilitate emptying, and discontinuation of tight or underwire bras.

Mastitis

As a single area of localized warmth, tenderness, edema, and erythema in one breast more than 10 days after delivery, mastitis may present with a sudden onset of breast pain, myalgia, and fever or with flulike symptoms. The infection commonly enters through a break in the skin, usually a cracked nipple; however, milk stasis from engorgement or obstruction from plugged ducts can also lead to mastitis. As reviewed in ABM Protocol 4, Mastitis (<http://www.bfmed.org/Resources/Protocols.aspx>), treatment includes antibiotics and continuation of breastfeeding with frequent feeding (or pumping) to allow drainage. Additional therapy includes good fluid intake, bed rest, and pain control.

Low Milk Supply

Actual low milk supply most often results from infrequent and/or ineffective feedings at the breast, introduction of formula

supplementation, which decreases breastfeeding frequency, or early (before 3 weeks) introduction of bottlefeeding, each of which can decrease milk supply because of inadequate milk removal. Primary treatment includes increased effectiveness and frequency of milk removal; galactagogues such as fenugreek (although not evidence based) may be helpful if use is temporary and supervised (Mortel and Mehta, 2013); ABM Clinical Protocol 9, Galactagogues (<http://www.bfmed.org/Resources/Protocols.aspx>), provides an additional summary. Maternal factors that reduce milk supply include primary or secondary hypoprolactinemia, absence of an intact adenohypophyseal axis, severe maternal illness, including sepsis or hemorrhage, prior breast surgery, use of estrogen-containing contraceptives, and severe fatigue, stress, or pain. It is not clear if maternal smoking actually reduces milk supply or is a behavioral risk factor for decreased duration of breastfeeding. Perceived low milk supply, in which the infant has a normal growth pattern but the mother believes she does not have sufficient milk, can result from growth spurts leading to increased infant demand, changes in the efficiency of the breast around 4 weeks leading to decreased apparent fullness before nursing, or increased efficiency of infant nursing beginning at 2 to 3 months leading to less frequent or shorter breastfeeding sessions. Infant weight check is diagnostic. Maternal depression may also contribute to maternal perception of low milk supply and is associated with early cessation of breastfeeding, so screening and treatment are essential (Dias and Figueiredo, 2015).

Contraception

The lactational amenorrhea method (LAM) is considered a sufficient criterion for “how to be reasonably sure a woman is not pregnant,” a formal endorsement of its contraceptive efficacy (Centers for Disease Control and Prevention, 2013) (Box 67.4). LAM and nonhormonal or barrier methods of contraception do not impact breast milk supply and are recommended if acceptable to the mother and her partner. For breastfeeding mothers, according to the US Medical Eligibility Criteria (MEC 1-4) grading system, intrauterine devices (IUDs), progestin-only contraceptive pills, implants (etonogestrel), and injectables (depot medroxyprogesterone acetate [DMPA]) are classified as MEC2 for use from 10 minutes after placental delivery to 1 month postpartum and MEC1 for use 1 month or more postpartum. The use of combined oral contraceptives (COCs) is contraindicated less than 21 days postpartum (MEC 3) (Centers for Disease Control and Prevention, 2013). Although the US Selected Practice Recommendations for Contraceptive Use, 2013, provides guidance to health providers, evidence is incomplete regarding the impact of hormonal methods on milk supply. A recent systematic review on this topic concluded that evidence was limited and conflicting and that the trials were of moderate to low quality: two of eight trials found a negative effect on breastfeeding duration (of COCs vs placebo and hormonal vs nonhormonal IUDs), and two of six trials found lower milk volume (with COCs vs placebo) (Lopez et al., 2015). A review focused on progestin-only contraception generally did not show an adverse impact on breastfeeding outcomes; however, evidence regarding the effect of early postpartum DMPA is methodologically weak (Brownell et al., 2012; Phillips et al., 2016.) Centers for Disease Control and Prevention guidelines (<http://www.cdc.gov/reproductivehealth/unintendedpregnancy/usmec.htm>) and ABM Clinical Protocol 13, Contraception and Breastfeeding (www.bfmed.org/Resources/Protocols.aspx), offer additional detail.

• BOX 67.4 US Medical Eligibility Criteria for Contraceptive Use

| | |
|-------|---|
| MEC 1 | No restriction (method can be used) |
| MEC 2 | Advantages generally outweigh theoretical or proven risks |
| MEC 3 | Theoretical or proven risks usually outweigh the advantages |
| MEC 4 | Unacceptable health risk (method not be used) |

From Centers for Disease Control and Prevention. U.S. medical eligibility criteria for contraceptive use, 2010: adapted from the World Health Organization Medical Eligibility Criteria for Contraceptive Use, 4th edition. MMWR Morb Mortal Wkly Rep. 2010;59(RR04):1–85.

Maternal Employment Outside the Home

Mothers who seek to combine breastfeeding and bottlefeeding or who face returning to work can offer one bottle of expressed milk daily from the time breastfeeding is established at 2 to 3 weeks of age: clinicians and mothers report that newborns who are unaccustomed to a bottle may refuse one if it is not introduced before 1 month of age. Although exclusive breastfeeding through 6 months with addition of complementary feeds and continued breastfeeding until 1 to 2 years of age is an evidence-based medical recommendation, mothers may face personal and work constraints. Health insurance plans now must cover the cost of a breast pump (Healthcare.gov, 2016). Although a double electric pump is considered the “gold standard” for optimal milk expression, a recent review found that low-cost interventions, including hand expression, breast warming, and relaxation tapes, may be as or more effective in specific situations (Becker et al., 2015). Supportive nonjudgmental information about flexible ways to combine working outside the home with breastfeeding should be offered. In addition to expressing and storing breast milk, mothers may want to identify reduced or flexible hours, take the infant to work, or breastfeed during breaks at a nearby childcare facility; working 19 hours or less per week was associated with a higher likelihood of continued breastfeeding regardless of the duration of maternity leave (Li et al., 2008; Galtry, 2015; Xiang et al., 2016).

Jaundice and Breastfeeding

“Breast-nonfeeding jaundice” and “breast milk jaundice” are distinct clinical entities, with differing approaches (Academy of Breastfeeding medicine protocol Committee, ABM Clinical Protocol 22, Jaundice, <http://www.bfmed.org/Resources/Protocols.aspx>; Preer and Philipp, 2011).

Breast-Nonfeeding Jaundice

Severe jaundice is the most frequent reason for readmission of late preterm and term infants, most of whom are breastfeeding. If there is any delay in lactogenesis II or if the infant has ineffective milk removal or infrequent sucking, less milk will be ingested and consequently less milk will be produced, leading to a cycle of decreased demand and decreased supply, with consequent “starvation jaundice” or breast-nonfeeding jaundice. The most common risk factor for inadequate milk removal is late preterm birth. The neonatal intestine has highly active glucuronidases, which cleave conjugated bilirubin to unconjugated bilirubin. The unconjugated bilirubin is readily reabsorbed and recirculated to the liver for conjugation. Milk alleviates bilirubin recirculation by providing calories and

gastrocolic stimulation. Thus treatment focuses on improving maternal lactation and providing milk (preferably expressed or donor human milk or formula) to the infant. Phototherapy should be initiated as per guidelines (Academy of Breastfeeding Medicine Protocol Committee, 2010).

Reports from the US Pilot Kernicterus Registry note that more than 90% of cases of kernicterus have been in breastfed infants, with late preterm infants and those with glucose 6-phosphate dehydrogenase (G6PD) deficiency overrepresented (Johnson, 2009). Primary prevention includes establishment of optimal lactation and measurement of total serum bilirubin concentrations at discharge and at the 3- to 5-day follow-up visit (AAP, 2015). Guidelines for families and providers are now also available (<http://www.cdc.gov/ncbddd/jaundice/index.html>).

Breast Milk Jaundice

In breastfed infants, total serum bilirubin concentrations remain elevated, and in a few infants this may last as long as 12 weeks. In formula-fed infants, serum bilirubin concentration declines, reaching values of less than 1.5 mg/dL by the 11th or 12th day after birth. It has been suggested that elevation in serum bilirubin concentration may be protective against oxidative injury since bilirubin has been shown to be an effective antioxidant in vitro. Infants with breastfeeding jaundice appear healthy and, other than jaundice, have completely normal physical examination findings and are growing normally. Mature human milk contains an unidentified factor that enhances the intestinal absorption of bilirubin in a susceptible host infant to produce jaundice. As the production of the factor diminishes over time and the liver matures, the serum bilirubin concentration eventually returns to normal. A direct bilirubin level should be measured to exclude biliary atresia, liver disease, sepsis, and other conditions, and an evaluation should exclude other causes of prolonged unconjugated hyperbilirubinemia such as galactosemia, hypothyroidism, urinary tract infection, pyloric stenosis, or low-grade hemolysis due to G6PD or other causes. Parents should be reassured, since there is no harm to the infant, and breastfeeding should not be interrupted unless the bilirubin level rises to reach phototherapy level (>20 mg/dL) (Preer and Philipp, 2011).

Collection and Storage of Human Milk

Electric breast pumps enable optimal milk production for mothers separated, either by employment or hospitalization, from their infant. General techniques for ensuring cleanliness during milk expression begin with good hand washing with soap and water; collection kits should be rinsed, cleaned with hot soapy water, and air dried. Bacteriologic testing is generally not necessary for milk collected for feeding to a mother's own infant. Milk can remain unrefrigerated for 6 to 8 hours, in an insulated cooler bag for 24 hours, and in a refrigerator for 5 days, each without significant bacterial proliferation (Centers for Disease Control and Prevention, 2016; Academy of Breastfeeding Medicine Protocol Committee, 2010). As described in ABM Clinical Protocol 8, Human Milk Storage (www.bfmed.org/Resources/Protocols.aspx), freezing is the preferred method of storing milk that will not be fed: single milk expressions should be packaged separately and labeled with the date (and the name of the infant if for center or hospital use). Unlike heat treatment, freezing preserves many of the nutritional and immunologic benefits of human milk, and pasteurization of the mother's own milk offers no additional benefit (Cossey et al.,

2013). When frozen appropriately, milk can be stored for as long as 6 months. Milk should never be thawed in a microwave oven, should be used within 24 hours, and should not be refrozen (Centers for Disease Control and Prevention, 2016).

Donor Human Milk

Donor milk generally refers to milk donated to a milk bank by a mother with excess supply, usually a woman who delivers a term infant and generally later in lactation. After rigorous screening processes, the milk is heat treated at 62.5°C for 30 minutes, the Holder pasteurization method. Donor milk is used primarily in NICUs to support the feeding of preterm neonates whose mothers have inadequate milk production to meet their neonates' needs (Arslanoglu et al., 2013). The Human Milk Banking Association of North America is a nonprofit entity founded in 1985 that has set guidelines for collection and pasteurization of milk and for use in NICUs. In 2016 there were 18 Human Milk Banking Association of North America milk banks in the United States and Canada (<https://www.hmbana.org/>).

The Holder pasteurization process results in a milk that is free of microbial contamination, but biologically and immunologically active factors may be affected adversely, including immunoglobulins, lactoferrin, lysozyme, erythropoietin, lipase, and insulin. The heat treatment does not affect oligosaccharides (which may be active in preventing NEC) (Ewaschuk et al., 2011; Arslanoglu et al., 2013). The donor milk carbohydrate content is generally preserved, but protein content may be low because milk is donated later in lactation from term mothers. The fat content of donor milk is also low because milk is not homogenized, and there are multiple transfers of the milk with loss of fat at each step (García-Lara et al., 2013).

Clinical studies on the use of donor human milk as compared with formula in the NICU suggest that it supports lower rates of NEC and better feeding tolerance but poorer growth and more biochemical abnormalities in nutritional status (Boyd et al., 2007; Quigley and McGuire, 2014). A randomized trial of donor milk versus preterm formula as supplements for inadequate volumes of the mother's own milk was conducted in preterm infants (Schanler et al., 2005). That appropriate matched study found no difference in the major outcome of NEC and/or late-onset sepsis between study groups. A parallel group that continued to receive only their mother's milk had significantly lower rates of these outcomes (Sullivan et al., 2010). The human milk groups in that study, however, also received bovine-based milk products containing intact bovine protein. An exclusive human milk diet, appropriately fortified with a human milk-derived fortifier, resulted in markedly lower rates of NEC and surgery for NEC, fewer parenteral nutrition days, and lower mortality compared with a diet containing intact bovine milk fortifier and/or formula (Sullivan et al., 2010; Cristofalo et al., 2013; Abrams et al., 2014). Thus donor milk is an alternative to the mother's own milk but not a replacement for it. Furthermore, a recent report showing that use of donor milk was associated with increasing use of mother's own milk suggests that use of donor milk may serve as a bridge to use of mother's own milk (Kantorowska et al., 2016).

The business of donor milk purchase by hospitals (and individuals) has created an industry of for-profit human milk banking (Prolacta Bioscience Monrovia, CA and Medolac Laboratories Lake Oswego, OR) that relies on paid donors: political and social issues include concern for diversion of milk from nonprofit banks. Milk selling and sharing over the Internet for personal use has become a relatively common practice outside medical venues; however, evidence regarding

spoilage, impurity (mixing with bovine milk), and contamination (infectious agents, caffeine, smoke exposure) is very discouraging, and the Food and Drug Administration advises against this practice (<http://www.fda.gov/ScienceResearch/SpecialTopics/PediatricTherapeuticsResearch/ucm235203.htm>; Geraghty et al., 2011; Keim et al., 2015).

Conclusion

In summary, evidence is compelling that breastfeeding significantly reduces all-cause mortality and the number and severity of infections in term and preterm infants in developed and developing countries. Strong evidence demonstrates that breastfeeding also promotes maternal health. Breastfeeding is also likely associated with long-term beneficial effects on infant health, growth, and development. Substantial increases are needed in the rates of breastfeeding, particularly among racial, ethnic, and socioeconomic subpopulations that have the highest infant morbidity and mortality rates. Healthcare practitioners are uniquely positioned to influence women in their decision to breastfeed and should not only collaborate with lactation specialists but should also be prepared to assist in the management of breastfeeding problems themselves. Discussion regarding the benefits of breastfeeding and the risks of formula permit the mother to make an informed infant feeding choice, and for many women, physician support is critical.

Suggested Educational Resources on the Web

- This list is neither exhaustive nor presented in a specific order but is intended as an introduction to Web-based educational materials that promote or inform about breastfeeding. All listed resources were cost-free at the time of this publication.
- Academy of Breastfeeding Medicine has clinical protocols related to breastfeeding, which are not intended as standards of care but offer informative guidelines. These are available at <http://www.guideline.gov> and at <http://www.bfmed.org/Resources/Protocols.aspx>.
- American Academy of Pediatrics has created The Breastfeeding Residency Curriculum Online Resource for program directors and other faculty. This resource offers "tools and resources about breastfeeding including clinical and cultural cases, prepared presentations about breastfeeding management, and evaluation and tracking tools" and is available at <http://www2.aap.org/breastfeeding/curriculum/>.
- Baby-Friendly USA Inc. is the official body for the Baby-Friendly Hospital Initiative in the United States. The website <https://www.babyfriendlyusa.org/> is an entry point for beginning work toward designation.
- Expanding Clinicians' Roles in Breastfeeding Support is a two-part online tutorial that provides 3 hours of content material that is compatible with the Baby-Friendly Hospital Initiative and serves to meet physician education requirements for Baby-Friendly Hospital Initiative certification: <http://www.hriainstitute.org/breastfeedingcme/>. The Stanford School of Medicine, Newborn Nursery at Lucile Packard Children's Hospital website "is designed to support the educational goals of our pediatric trainees" and is a resource for all healthcare providers promoting breastfeeding. Multiple video clips are included: <http://newborns.stanford.edu/Breastfeeding/>.
- LactMed is a database with information on the safe use of medications during lactation and is located on the National Library of Medicine's ToxNet at <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>.
- LaLeche League is an international organization dedicated to providing information and support to breastfeeding mothers: <http://www.llli.org/>.
- Wellstart International's *Lactation Management Self-Study Modules Level 1* (4th ed) is an educational tool with clinical cases in a question-answer format and is intended for health professionals interested in breastfeeding. The link <http://www.wellstart.org> provides access to a free download for the first three modules, with a webpage of links to promote breastfeeding at <http://www.wellstart.org/links.html>.

Enteral Nutrition for the High-Risk Neonate

TARAH T. COLAIZY, SARA B. DEMAURO, KERA M. MCNELIS,
AND BRENDA B. POINDEXTER

KEY POINTS

- Early protein intake is associated with improved growth and neurodevelopmental outcomes in premature infants; achieving adequate intake requires a combined parenteral and enteral approach.
- Maternal human milk is the preferred diet for preterm infants; further research is needed to develop evidence-based clinical guidelines for the use of donor human milk when maternal milk is unavailable.
- For very low birth weight infants, unfortified human milk contains insufficient protein, energy, and many essential micronutrients, requiring supplementation with milk fortifier and/or multivitamin products.
- Postnatal growth failure remains a common complication of preterm birth and is associated with adverse outcomes; optimization of growth outcomes requires attention not only to weight gain but also to appropriate linear growth and body composition both in the neonatal intensive care unit and following hospital discharge.

Providing optimal enteral nutrition to high-risk premature neonates is a difficult clinical challenge. To achieve optimal growth, nutritional needs in the early neonatal period are greater than at any other time of life. Premature delivery results in decreased nutrient deposition in the infant. Critical illness and immature gut motility and function often preclude intended delivery of nutrition. Despite the lack of evidence, fear of necrotizing enterocolitis (NEC) if feedings are advanced too quickly may also limit provision of optimal enteral nutrition. Consequently, the premature infant requires specialized nutritional support to meet these great demands for growth.

Current recommendations for provision of enteral nutrition to premature infants are based on the illusive goal of duplicating rates of intrauterine accretion of the fetus at the same postmenstrual age. However, this goal is rarely accomplished, and the incidence of postnatal growth failure in very low birth weight (VLBW) infants remains unacceptably high. Data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network revealed growth failure at 36 weeks' postmenstrual age in 79% of VLBW infants (Stoll et al., 2010). Infants who experience one or more major morbidities such as bronchopulmonary dysplasia (BPD), severe intraventricular

hemorrhage, NEC, or late-onset sepsis are at increased risk of growth failure. The association between suboptimal postnatal growth and poor neurodevelopmental outcomes is especially worrisome and emphasizes the importance of optimizing nutritional support for premature infants in the neonatal intensive care unit (NICU).

Special considerations regarding nutrient needs of premature infants arise at birth. Because of limited body stores, increased energy expenditure, severity of illness, and/or immaturity and inability to tolerate enteral feedings, premature infants are given parenteral nutrition immediately after birth. However, to meet nutrient requirements, a combined approach with both parenteral and enteral nutrition is imperative to achieve optimal growth outcomes and minimize morbidities such as NEC. This chapter describes the basis of recommendations for enteral nutrient support for high-risk neonates. In addition, evidence regarding the initiation and advancement of enteral feedings in premature infants is discussed. Finally, special considerations for enteral nutrition after discharge from the NICU are reviewed.

Macronutrient Requirements

Protein

When fetal life is interrupted by premature birth, significant protein deficits can occur and may be difficult if not impossible to recoup (Embleton et al., 2001). Several observational studies have found an association between early protein intake and postnatal growth in extremely premature infants (Berry et al., 1997; Olsen et al., 2002). In addition, there is increasing evidence that the amount of protein intake early in life correlates with improved neurodevelopmental outcomes. To optimize growth outcomes, particular focus must therefore be given to enteral protein intake.

The most commonly accepted goal of provision of enteral nutrition to premature infants is to achieve growth comparable with that of the fetus. At 26 weeks' gestation the fetus accretes approximately 2.2 g/kg per day; of protein by term, this amount declines to approximately 0.9 g/kg per day. Protein losses are inversely related to gestational age, providing an explanation for the higher protein requirements in extremely premature neonates. Accretion of protein is dependent on protein quantity and quality, energy intake, and underlying disease states (such as sepsis or

TABLE 68.1 Estimated Protein and Energy Requirements to Achieve Fetal Growth

| Weight (g) | Protein (g/kg per day) | Energy (kcal/kg per day) | Protein/Energy (g/100 kcal) |
|------------|------------------------|--------------------------|-----------------------------|
| 500–700 | 4.0 | 105 | 3.8 |
| 700–900 | 4.0 | 108 | 3.7 |
| 900–1200 | 4.0 | 119 | 3.4 |
| 1200–1500 | 3.9 | 125 | 3.1 |
| 1500–1800 | 3.6 | 128 | 2.8 |
| 1800–2200 | 3.4 | 131 | 2.6 |

Based on the factorial method (Ziegler et al., 2002).

surgical stress), as well as concomitant medications (such as systemically acting steroids, fentanyl, and insulin).

Protein requirements in premature infants have been estimated with use of a variety of methods, including fetal animal models, the factorial approach, and estimates based on the composition of human milk. Protein requirements estimated with the factorial approach for premature infants weighing 500–1200 g are shown in Table 68.1; with increasing body weight, protein requirements determined by the factorial approach decrease (Ziegler et al., 2002). Protein and energy needs should be considered hand in hand because protein synthesis requires energy. Extremely premature infants require a higher protein-to-energy ratio for optimal growth. Protein retention, or balance, is generally a function of protein intake if energy intake is adequate. Enteral protein requirements are calculated to be higher than parenteral ones because only approximately 85% of enteral protein is absorbed. In contrast to empiric methods, this approach does not take into consideration nutrient requirements for catch-up growth.

On the basis of currently available evidence and consensus of an expert panel, 3.5–4.5 g of protein per kilogram per day is recommended for fully enterally fed VLBW infants (Koletzko et al., 2014). Further studies are required to more clearly define the upper limit of enteral protein intake in premature neonates to optimize growth and neurodevelopmental outcomes.

Energy

In utero the fetus utilizes both glucose and amino acids as a source of energy. If energy intake is not adequate, protein utilization is not efficient, resulting in lower retention of nitrogen. As shown in Table 68.1, Ziegler et al. (2002) have estimated that energy requirements are lower in infants with lower body weight. Coupled with the inverse relationship between protein requirements and weight, the protein-to-energy ratio required to achieve fetal growth is highest in the most premature infants. The recommended energy intake for enterally fed premature infants ranges between 110 and 130 kcal/kg per day (Koletzko et al., 2014).

The optimal ratio of enteral protein to energy intake must be defined not only in terms of optimizing weight gain but also by that which achieves optimal body composition. Consequently, attempting to duplicate the intrauterine environment may not be appropriate for extrauterine life, given differences in nutrient supply

and metabolism. Changes in body composition in response to energy intake are an important consideration, because excessive energy intake can contribute to excessive fat deposition, and recent studies have suggested that rapid weight gain may be associated with adverse outcomes.

The energy needs of the neonate are derived from a computation of the energy expenditure, energy storage, and energy losses. Energy expenditure consists of the energy needed to cover the resting metabolic rate, activity, thermoregulation, and the energy cost of growth. Energy storage consists of the energy (fat and lean mass) deposited for growth. Energy losses are usually due to incomplete absorption of nutrients and are greater in premature infants than in term infants or adults. The largest component of the total estimated energy requirement is that needed for the resting metabolic rate. When nourished parenterally, the premature infant has less fecal energy loss, generally fewer episodes of cold stress, and somewhat lesser activity, so the actual energy needs for growth are lowered to approximately 85–95 kcal/kg per day. In the case of chronic disease, such as BPD, the resting energy expenditure rises significantly. Total energy needs in premature infants with BPD are increased because of greater energy expenditure, activity, and fecal energy losses. It is not surprising to find that these infants may require 150 kcal/kg per day to achieve weight gain.

Carbohydrates

The main carbohydrate in human milk is lactose, supplying nearly half of the total calories. Lactase (β -galactosidase) is an intestinal enzyme that hydrolyzes lactose to glucose and galactose in the small intestine. Despite lower levels of intestinal lactase activities in premature infants, they are able to efficiently digest lactose. Nonetheless, many infant formulas designed for premature infants supply glucose polymers. Glucose polymers are digested by α -glucosidases; the activity level of these enzymes approximates adult levels much sooner than does that of β -galactosidase, which theoretically makes glucose polymers easier for the premature infant to digest than lactose. Glucose polymers also have an advantage in that they increase caloric density without a rise in osmolality. The recommended carbohydrate intake for premature infants is 11.6–13.2 g/kg per day (Koletzko et al., 2014). This amount of intake will provide sufficient glucose to meet the needs for total energy expenditure.

Fat

Fat provides a substantial source of energy for growing premature infants. Premature infants have low levels of pancreatic lipase, bile acids, and lingual lipase. Human milk, however, supplies a variety of lipases, including lipoprotein lipase, bile salt esterase, and nonactivated lipase. The composition of dietary fat affects absorption and digestion. The absorption of fatty acids increases with decreasing chain length and with the degree of unsaturation. Consequently, medium-chain triglycerides (carbon chain length of 6–12) are hydrolyzed more readily than long-chain triglycerides. In contrast to formulas designed for term infants, premature infant formulas supply medium-chain triglycerides. Human milk supplies 8%–12% of fat as medium-chain triglycerides. The recommended intake for lipid in enterally fed premature infants ranges between 4.8 and 6.6 g/kg per day (Koletzko et al., 2014). Of this amount, medium-chain triglycerides should account for less than 40% of total intake.

Micronutrients, Vitamins, Minerals, and Trace Element Requirements

Calcium and Phosphorus

Calcium and phosphorus are primary components of the skeleton, accounting for 99% and 85%, respectively, of bone mass. The goal for premature infant nutrition is to achieve a bone mineralization pattern similar to that in the fetus and to avoid osteopenia and fractures. The peak fetal calcium accretion rate occurs in late gestation through active calcium influx (Bhatia et al., 2013). Infants will have greater calcium and phosphorus needs when exposed to diuretics, which increase renal excretion of these minerals. Phosphorus requirements may be greater in the setting of a history of placental insufficiency, and calcium requirements may be greater for infants exposed to theophylline or steroids.

Preterm human milk contains approximately 250 mg of calcium and 140 mg of phosphorus per liter. Metaanalysis of breast milk content studies reveals calcium and phosphorus levels that are similar in preterm and term milk (Gidrewicz and Fenton, 2014). The calcium and phosphorus contents of enteral formula products designed for premature infants in the United States are significantly greater. In human milk, calcium and phosphorus exist in ionized and complexed forms that are easily absorbed. Thus in the design of commercial formulas, greater quantities of these minerals are added to compensate for their poorer bioavailability, so additional supplementation is not necessary (Bhatia et al., 2013). However, distinct from the term infant, the premature infant requires significantly greater quantities of calcium and phosphorus than can be provided in human milk.

For the human milk–fed premature infant, calcium and phosphorus are deficient throughout lactation, and the levels are far below those necessary to achieve respective intrauterine accretion rates. Deficient intakes of calcium and phosphorus are associated with biochemical markers such as low serum and urine phosphorus concentrations, elevated serum alkaline phosphatase activity, and elevated serum and urine calcium concentrations. Usually, serum phosphorus concentrations are the best indicators of calcium and phosphorus status in human milk–fed premature infants, and serum phosphorus concentration below 4 mg/dL should be followed up carefully. Monitoring of these laboratory markers should be undertaken during hospitalization of VLBW infants (Abrams and Committee on Nutrition, 2013). The American Academy of Pediatrics (AAP) Committee on Nutrition issued guidelines that laboratory monitoring of VLBW infants should begin at 4 to 5 weeks after birth. Prolonged deficiency of these minerals tends to stimulate bone resorption to normalize serum calcium concentrations. This bone activity is often correlated with elevated serum alkaline phosphatase activity. It has been reported that most premature infants who had an elevated serum alkaline phosphatase activity were those fed human milk. Moreover, follow-up evaluations of the same infants at 9 and 18 months noted that linear growth was significantly lower in the group that had the higher serum activity of alkaline phosphatase in the neonatal period. A high alkaline phosphatase value in the neonatal period is a negative predictor of height in 9- to 12-year-old adolescents (Fewtrell et al., 2000). Serum alkaline phosphatase levels greater than 800 international units (IU)/L or clinical concern for fractures should lead to a radiographic work-up for rickets. Dual-energy X-ray absorptiometry and quantitative ultrasonography are increasingly used as tools for studying metabolic bone disease in preterm infants but have variable clinical availability (Rack et al., 2012; Rehman

and Narchi, 2015). Diagnosis of rickets by US neonatologists is most commonly performed by X-ray (Kelly et al., 2014).

The supplementation of human milk with both calcium and phosphorus not only improves the net retention of both minerals but also increases bone mineral content. Current management of human milk–fed premature infants emphasizes the need for supplements of both calcium and phosphorus. A linear relationship exists between calcium (or phosphorus) intake and net retention in enterally fed premature infants. Premature infants receiving unfortified human milk never achieve intrauterine accretion rates for calcium and phosphorus. Daily intakes of calcium at approximately 200 mg/kg per day and phosphorus at 100 mg/kg per day can be achieved with the use of specialized human milk fortifiers (HMFs) and preterm formulas, thus making it possible to meet intrauterine estimates. HMFs contain highly soluble calcium glycerophosphate, promoting calcium retention (Bhatia et al., 2013). However, term infant formulas and specialized (not “preterm”) formulas provide inadequate quantities of calcium and phosphorus to meet the needs of growing premature infants. Several factors affect the absorption of calcium and phosphorus, including postnatal age and intake of calcium, phosphorus, lactose, fat, and vitamin D. Calcium absorption increases with a low-pH environment and high-casein, high-lactose formula. Loss of calcium content is seen with continuous gavage feeding of breast milk (Rogers et al., 2010). Vitamin D, however, is responsible for only a small component of calcium absorption in premature infants.

The time to supply sufficient calcium and phosphorus stores for premature infants is during the initial hospitalization, before their discharge and the beginning of exclusive breastfeeding. However, because of the need for prolonged parenteral nutrition and the inability to provide “catch-up” quantities of calcium and phosphorus in milk, some infants may benefit from additional calcium and phosphorus after hospital discharge through the use of transitional formulas. Preterm infants discharged on an exclusive breast milk diet may require continued monitoring of biochemical markers.

Magnesium

Approximately 60% of body magnesium is in bone. Magnesium has the highest fetal accretion rate in the third trimester. Preterm human milk contains approximately 30 mg of magnesium per liter. The absorption of magnesium is significantly greater from unfortified human milk than from formula. The needs of preterm infants are 8–15 mg/kg per day (Bhatia et al., 2013), and net magnesium retention in human milk–fed premature infants meets intrauterine estimates. Hypomagnesemia may be present in infants of diabetic mothers and is frequently transient. Sometimes hypomagnesemia may reduce parathyroid hormone secretion and responsiveness and will require correction to achieve normocalcemia.

Trace Elements

Premature infants are particularly susceptible to trace element deficiencies given that most accrual occurs during the last third of pregnancy. The literature on trace mineral requirements for premature infants is sparse, as are studies to support evidence-based guidelines for provision of these nutrients (Finch, 2015).

Zinc

Several factors affect the zinc needs of the enterally fed premature infant. Fetal accretion of zinc is approximately 0.85 mg/kg per

day. Growth is a major determinant of zinc needs. Premature infants receiving pooled pasteurized human milk (zinc intake of approximately 0.7 mg/kg per day) are in negative zinc balance for 60 days postnatally and never meet the intrauterine accretion rate. In contrast, intakes of 1.8–2 mg/kg per day are associated with a net retention of zinc that surpasses intrauterine accretion rates. A zinc-to-copper ratio of less than 20:1 is recommended for preterm infants.

The major excretory route is via the gastrointestinal (GI) tract. Infants with large GI fluid losses may become zinc deficient, and patients with short bowel syndrome may require 400–800 µg/kg per day. The classic signs of zinc deficiency include an erythematous dermatitis over mucous membranes, facial areas, and the extremities. Symptomatic zinc deficiency presents with susceptibility to infection, impaired wound healing, and failure to thrive.

Plasma zinc values lower than 50 µg/dL are highly suggestive of deficiency, but this is not a reliable biomarker for marginal deficiency, and levels may be falsely elevated in times of bone remodeling. Blood zinc levels are lower in extremely critically ill preterm infants (Wang et al., 2015). Levels should be measured in the context of large stool or ostomy losses. A very low activity of serum alkaline phosphatase, a zinc-dependent enzyme, is also suggestive of deficiency. Reports of symptomatic zinc deficiency in unsupplemented human milk–fed premature infants serve as a reminder of the decline in milk zinc concentration as lactation advances.

Copper

No universally accepted methods exist to assess copper status clinically. Balance study data provide only an estimate of copper retention at one point in time. Premature infants receiving pooled pasteurized human milk (copper intake of approximately 85 µg/kg per day) are in negative copper balance for 30 days postnatally and never meet the intrauterine accretion rate. Copper concentration is high in early breast milk and decreases throughout lactation. Human milk fortifier supplies additional copper. Symptoms of copper deficiency include osteopenia, neutropenia, and hypochromic anemia. Copper retention is negatively correlated to zinc intake and postnatal age (Bhatia et al., 2013). Copper deficiency may also present as metabolic bone disease with osteoporosis, metaphyseal changes, and physeal disruption (Marquardt et al., 2012). Because copper is excreted in bile, cases of severe cholestasis warrant limitation of copper intakes.

Selenium

Selenium is an essential trace element and is actively transported from the mother to the fetus (Kantola et al., 2004). It may have an important role in oxidative damage from organic hydroperoxides and may be protective of the toxicity of maternal exposure to polycyclic aromatic hydrocarbons, which may be one contributor to preterm delivery (Huel et al., 2000). Low maternal selenium status in early gestation may increase the risk of preterm premature rupture of membranes (Rayman et al., 2011). In randomized controlled trials the incidence of premature rupture of membranes was lower in a group of pregnant women who received selenium supplementation (Tara et al., 2010). Further research is needed to clarify the role of selenium in adverse pregnancy outcomes as most study designs are limited in the ability to determine causal relationships (Mariath et al., 2011). A Cochrane review of three eligible trials (two of which were done in geographic regions with low population selenium levels) reported an association between selenium supplementation to premature infants and a reduced risk of sepsis (Darlow and Austin, 2003).

Iron

The iron needs of the premature infant are determined by birth weight, initial hemoglobin concentration, rate of growth, and magnitude of iron loss and/or volume of transfused blood. Iron endowment may be diminished by growth restriction and placental insufficiency in preterm infants (McCarthy et al., 2016). Optimization of umbilical cord clamping practices results in increased iron stores (Oh et al., 2011; Rabe et al., 2012). Postnatal iron metabolism occurs in three phases. In the first phase, there is decreased erythropoiesis. The hemoglobin concentration declines to a nadir, physiologic anemia of prematurity, which is at approximately 2–3 months of postnatal age. In the second phase, the hemoglobin concentration rises as active red cell production is occurring. In this phase, iron is needed. The third phase is an exhaustion of iron stores, or late anemia of prematurity, observed if iron supplementation is inadequate.

The concentration of iron in human milk declines throughout lactation. Premature infants fed human milk are in negative iron balance, which, in the absence of transfusion, can be corrected with iron supplements. Iron absorption also appears to be facilitated by a modest degree of anemia. The most recent recommendation from the AAP Committee on Nutrition is to begin enteral iron supplementation of 2 mg/kg per day by 1 month of age in preterm infants fed human milk (Baker et al., 2010). This may be delayed in preterm infants who have received multiple erythrocyte transfusions, as each milliliter of transfused blood delivers 1 mg of elemental iron, leading to risk of excessive iron stores (Park and Kim, 2015; Rehman and Narchi, 2015). Enteral iron supplementation is safer than parenteral iron dosing. Formula-fed premature infants should receive iron-fortified formula from the onset of milk feeding. At 6 months of age, term infants should receive 11 mg/day (Baker et al., 2010). Iron supplementation significantly decreases the prevalence of iron-deficiency anemia (Long et al., 2012).

CONTROVERSY BOX

Although it is clear that preterm infants will require iron supplementation, the optimal timing of initiation of supplementation and the duration of use are less clear (Mills and Davies, 2012; Taylor, Kennedy, 2013). There is mixed evidence on the effects of iron supplementation and improved neurodevelopmental outcomes (Long et al., 2012). Dysregulation of the iron ion homeostasis pathway mediating oxidative damage may contribute to the mechanism for retinopathy of prematurity pathophysiology (Luo et al., 2015). Latent iron deficiency is associated with abnormal auditory neural maturation in late preterm infants (Choudhury et al., 2015). Early iron supplementation results in a higher nadir of hemoglobin and serum ferritin concentrations but may also result in iron overload (Jin et al., 2015).

Sodium and Potassium

Premature infants generally need more sodium per unit of body weight than is needed by term infants. Historical studies proposed that this increased need was due to immature renal sodium conservation mechanisms, but more recent studies of very preterm infants have revealed defective aldosterone secretion with conserved renal aldosterone sensitivity (Martinerie et al., 2015). Sodium wasting is inversely related to gestational age. A study comparing daily sodium intakes of 2.9 and 1.6 milliequivalent (mmol)/kg in premature infants suggested that the former intake provided more appropriate serum sodium concentrations. Hyponatremia also may occur in premature infants primarily fed human milk because the sodium content of preterm milk continues to decline throughout lactation (Dutta et al., 2014), although studies have revealed that there is a significant increase in the sodium concentration of donor

breast milk after 1 year postpartum (Perrin et al., 2017). Early sodium supplementation prevents hyponatremia in very preterm infants and may enhance weight gain (Isemann et al., 2016). The need for these electrolytes may increase during or after diuretic use. Infants with short gut or ostomies may have increased sodium needs, and urinary sodium measurements are a good correlate for growth (Mansour et al., 2014).

Vitamins

The fat-soluble vitamins A, D, E, and K are stored in the body, and large doses may result in toxicity. Water-soluble vitamins—thiamine, riboflavin, niacin, vitamin B₆, folate, vitamin B₁₂, pantothenic acid, biotin, and vitamin C—are not stored in the body, and excess intakes are excreted in the urine or bile (vitamin B₁₂). The intake of water-soluble vitamins should therefore be monitored at frequent intervals to avoid deficiency states. Vitamin A and riboflavin concentrations decline in human milk under conditions of light exposure and after passage through feeding tubes. As a consequence of exposure to air, ascorbic acid concentrations are lower in pooled human milk. Pasteurization of donor breast milk leads to reduction in vitamin D content (Gomes et al., 2016). Supplementary vitamins are provided in HMFs and in preterm formulas. A multivitamin supplement should be given to preterm infants once feedings change to unfortified human milk or standard formula.

Vitamin A

The reported vitamin A content of preterm breast milk is variable but is similar to that of term breast milk. The content is highest in colostrum (400–600 IU/dL) and in breast milk with a higher fat content and declines in mature lactation (60–200 IU/dL). The system of handling of breast milk, including bottlefeeding, may decrease the concentration of retinol (Francis et al., 2012).

The optimal dosing of vitamin A supplementation needs further study (Moya, 2014). Metaanalyses reveal that vitamin A supplementation may result in a modest reduction in the risk of BPD or death, as low tissue vitamin A and retinol-binding protein levels are associated with decreased clearance of lung secretions and decreased ability to repair lung tissue (Darlow and Graham, 2011). However, these studies are confounded by the use of dexamethasone in preterm infants, which results in a transient rise then fall in serum retinol and retinol-binding protein levels. Furthermore, there is evidence that there is a higher risk of sepsis with vitamin A administration (Mactier, 2013; Ubers et al., 2014).

CONTROVERSY BOX

There is emerging evidence that retinoic acid, a vitamin A metabolite, may have a role in prevention of retinopathy of prematurity (Mactier et al., 2012; Wang et al., 2014).

Vitamin D

Conflicting guidelines are proposed by different professional organizations regarding the optimal dosing of vitamin D. The AAP Committee on Nutrition issued guidelines establishing the amount of recommended vitamin D as 400 IU/day for infants. The recommendation applies to infants receiving human milk and those who are consuming less than 1 quart of infant formula per day and is based in part on the risk of rickets in exclusively breastfed infants who do not receive supplementation with 400 IU of vitamin D per day. This level of supplementation is sufficient to meet a target

plasma 25-hydroxyvitamin D concentration of 50 mmol/L in most infants (Abrams and Committee on Nutrition, 2013; McCarthy et al., 2013). However, the Endocrine Society recommends that infants may require up to 1000 IU/day to meet a target plasma 25-hydroxyvitamin D concentration of 75 mmol/L for nonskeletal health benefits (Nehra et al., 2013).

Antiepileptic drugs such as phenytoin and phenobarbital may affect vitamin metabolism. Ethnicity has a role in serum 25-hydroxyvitamin D levels, with Hispanic infants having a lower umbilical cord blood level (Abrams et al., 2012). Preterm infants are at higher risk of being born with lower 25-hydroxyvitamin D umbilical cord serum levels (Burris et al., 2014).

CONTROVERSY BOX

Certain vitamin D receptor polymorphisms are associated with increased frequency of BPD (Koroglu et al., 2014). Lower maternal and neonatal serum 25-hydroxyvitamin D levels are associated with BPD in preterm infants (Cetinkaya et al., 2015; Fettah et al., 2015). Recent studies have revealed that vitamin D supplementation in black preterm infants is associated with more recurrent wheezing (Hibbs et al., 2015). A randomized clinical trial of different vitamin D dosing strategies for black preterm infants is under way.

Vitamin E

A single enteral dose of vitamin E supplementation raises the serum levels of α -tocopherol, the biologically active form, in preterm infants (Bell et al., 2013). Colostrum has high concentrations of α -tocopherol in both term and preterm milk (Grilo et al., 2013). The system of handling breast milk, including bottlefeeding, may decrease the concentration of α -tocopherol (Francis et al., 2012). There is a high prevalence of vitamin E deficiency in VLBW infants until term-corrected gestational age (Kositamongkol et al., 2011). Vitamin E supplementation reduces the risk of retinopathy of prematurity and intracranial hemorrhage and increases the risk of sepsis in VLBW infants (Brion et al., 2003). Long-term (>6 months) α -tocopherol supplementation in extremely low birth weight (ELBW) infants may increase performance intelligence quotient (Kitajima et al., 2015).

Vitamin K

In the United States, phytonadione (vitamin K) is routinely administered at birth by intramuscular injection to prevent hemorrhagic disease of the newborn. There are oral dosing regimens reported in the literature, but there is a lack of evidence to support routine alternative use (Ipema, 2012). Genetic polymorphisms in the vitamin K–dependent coagulation system may make some preterm infants be at higher risk of developing intraventricular hemorrhage (Schreiner et al., 2014). Proteins induced by vitamin K absence are the most sensitive indicators of vitamin K status, but prothrombin time and coagulation studies are commonly used.

Options for Enteral Nutrition

When clinicians are considering enteral feeding in preterm infants, there are several basic choices that they must make. First and foremost is the choice of base diet for the infant, with three options commonly used: maternal milk, donor human milk, or preterm formula. Once this decision has been made, clinicians must decide (1) when to initiate enteral feeding, (2) how to advance the feeding volumes, and (3) how to feed the infant (by mouth, by gravity bolus via a nasogastric (NO)/orogastric (OG) tube, by timed or continuous infusion via NG/OG tube). Because of the specific

nutritional needs of preterm infants (primarily the requirement for higher protein and mineral intake than that provided by human milk alone), there is an additional decision to be made, and that is determining when human milk fortification will be initiated and how to manage ongoing milk fortification.

Human Milk

Maternal Milk

Maternal human milk is the preferred diet for preterm infants, in almost all circumstances. Observational studies conducted in the past 30 years have demonstrated that preterm infants fed maternal milk experience health benefits compared with those fed preterm formula, including reduced risk of common complications of prematurity such as late-onset sepsis, NEC, and BPD (Lucas and Cole, 1990; Schanler et al., 1999, 2005; Vohr et al., 2006; Sisk et al., 2007; Maayan-Metzger et al., 2012). Additionally, VLBW infants fed maternal milk have been shown to require fewer rehospitalizations (Vohr et al., 2006) and to have superior developmental outcomes at 2 to 8 years of age (Lucas et al., 1992), with demonstration of a significant dose–response relationship (Vohr, 2007). Maternal milk diets are recommended for preterm infants by the AAP, the World Health Organization (WHO), and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (Agostoni et al., 2010; Section on Breastfeeding, 2012). Although rates of initiation of breast milk expression are increasing among mothers of VLBW infants (Colaizy and Morris, 2008), mothers are sometimes unable to produce the required volume of milk (Jegier et al., 2013) or have medical contraindications to breastfeeding (Neifert, 2001). In these circumstances, donor human milk or preterm formula must be used to replace or supplement maternal milk. This section will address human milk, both maternal and donor.

Human Milk Nutrient Content

Protein

In the first few weeks after birth the protein content of milk from mothers who deliver premature infants (preterm milk) is greater

than that of milk obtained from mothers who deliver term infants (term milk). The protein content of both preterm milk and term milk declines over time, such that beyond 2 weeks it levels off to that which is termed *mature milk*. The quality of protein—the proportion of whey and casein—in human milk is particularly suitable for the premature infant. Human milk contains 70% whey and 30% casein, whereas bovine milk contains 18% whey and 82% casein. The whey fraction of milk consists of soluble proteins that remain in solution after acidification and thus are digested more easily. Human milk promotes more rapid gastric emptying than both casein- and whey-dominated bovine milk.

The major human whey protein is α -lactalbumin, a nutritional protein for the infant and a component of mammary gland lactose synthesis. Lactoferrin, lysozyme, and secretory immunoglobulin A (sIgA) are specific human whey proteins that are particularly resistant to hydrolysis and, as such, line the GI tract to play a primary role in host defense. These proteins can therefore provide protection for the premature infant who is exposed to multiple pathogens in the nursery environment.

Although the protein content of human milk from mothers who deliver prematurely is initially higher than the protein content of human milk from mothers who deliver at term, the protein content of preterm human milk declines over time, much more quickly than has been generally thought. Pooled data from multiple small trials in the 1980s have demonstrated an initial protein content of preterm human milk of approximately 1.9 g/dL at 1 week after birth, declining to 1.2 g/dL by 30 days, and these values are typically used for calculations of estimated protein content of human milk fed to preterm infants (Schanler and Oh, 1980; Gross et al., 1981; Lemons et al., 1982; Picciano, 2001). Similarly, the protein content of milk produced by mothers delivering at term is typically estimated to be 1 g/dL. Gidrewicz and Fenton (2014) published a metaanalysis of 41 studies of human milk composition performed over 30 years, representing more than 3000 mothers. They report protein content of preterm milk in the first week of lactation as 2.2 g/dL, declining to 1.4 g/dL by week 3, and 1 g/dL by week 10 (Table 68.2). These values should be kept in mind when one is estimating protein intake of preterm infants fed human milk.

TABLE 68.2 Composition of Preterm and Term Human Milk

| | Energy (kcal/dL) | Protein (g/dL) | Fat (g/dL) | Lactose (kcal/dL) | Oligosaccharides (g/dL) |
|----------------|------------------|----------------|---------------|-------------------|-------------------------|
| Preterm | | | | | |
| Week 1 | 60 (45–75) | 2.2 (0.3–4.1) | 2.6 (0.5–4.7) | 5.7 (3.9–7.5) | 2.1 (1.3–2.9) |
| Week 2 | 71 (49–94) | 1.5 (0.8–2.3) | 3.5 (1.2–5.7) | 5.7 (4.1–7.3) | 2.1 (1.1–3.1) |
| Week 3–4 | 77 (61–92) | 1.4 (0.6–2.2) | 3.5 (1.6–5.5) | 6.0 (5–7) | 1.7 (1.1–2.3) |
| Week 10–12 | 66 (39–94) | 1.0 (0.6–1.4) | 3.7 (0.8–6.5) | 6.8 (6.2–7.2) | NA |
| Term | | | | | |
| Week 1 | 60 (44–77) | 1.8 (0.4–3.2) | 2.2 (0.7–3.7) | 5.8 (4.2–7.4) | 1.9 (1.1–2.7) |
| Week 2 | 67 (47–86) | 1.3 (0.8–1.8) | 3.0 (1.2–4.8) | 6.2 (5–7.3) | 1.9 (1.1–2.7) |
| Week 3–4 | 66 (48–85) | 1.2 (0.8–1.6) | 3.3 (1.6–5.1) | 6.7 (5.3–8.1) | 1.6 (1–2.2) |
| Week 10–12 | 68 (50–86) | 0.9 (0.6–1.2) | 3.4 (1.6–5.2) | 6.7 (5.3–8.1) | NA |

Fat

Fat provides 50% of the energy in human milk. The lipid system in human milk is structured in a way that facilitates fat digestion and absorption. In human milk, fat exists as organized fat globules containing an outer protein coat and an inner lipid core. The type of fatty acids (high palmitic 16:0, oleic 18:1, linoleic 18:2 ω -6, and linoleic 18:3 ω -3), their distribution on the triglyceride molecule (16:0 at the 2-position of the molecule), and the presence of bile salt-stimulated lipase are important components of the lipid system in human milk. Fat content of preterm milk is higher than that of term milk in the first 2 weeks (2.2–3.5 g/dL in preterm milk vs 1.8–3.0 g/dL in term milk) (Gidrewicz and Fenton, 2014). However, fat is the most variable macronutrient in human milk (Table 68.2). Fat content of human milk differs among women, changes during the day, rises slightly during lactation, and increases dramatically within a single milk expression. The variability in total fat content is unrelated to maternal dietary fat intake. Because it is not homogenized, the fat separates out of human milk on standing. The separated fat may adhere to collection containers, feeding tubes, and syringes and thus may not be delivered to the infant, compromising energy intake.

The variability in the fat content of human milk may be used to advantage in the premature infant. Most milk transfer during a feeding occurs in 10 to 15 minutes, but continued milk expression yields a milk with a progressively higher fat content—the hindmilk—than the earlier foremilk. The fat content of hindmilk may be 1.5- to 3-fold greater than that of foremilk. The use of hindmilk in selected cases may provide the premature infant with additional energy. Hindmilk and foremilk contain similar concentrations of nitrogen, calcium, phosphorus, sodium, and potassium. Copper and zinc concentrations decline by approximately 5% from foremilk to hindmilk.

The differences between foremilk and hindmilk should also be considered in terms of the distribution of calories. Fat and protein account for 42% and 12%, respectively, of the calories in foremilk and 55% and 9% of the calories in hindmilk. The long-term feeding of hindmilk thus could have a negative effect on protein status. A greater proportion of protein calories (10%–12%) is recommended for premature infants. The variability in the fat content of human milk may be used to advantage in the premature infant.

Carbohydrate

The major carbohydrate in human milk is lactose, a disaccharide composed of the monosaccharides galactose and glucose. Lactose content is similar between preterm human milk and term human milk and does not vary with the duration of lactation as protein and fat contents do. Small amounts of free glucose and galactose are also present in human milk. Human milk also contains a large amount of oligosaccharides (human milk oligosaccharides [HMO]), complex sugars composed of disaccharide chains built of lactose, galactose, *N*-acetylglucosamine, and *N*-acetylneuraminic acid, modified by fucose and sialic acid. HMOs represent the largest carbohydrate fraction in human milk other than lactose (5%–10% of total carbohydrate) and are often present in similar amounts as protein (Table 68.2). These carbohydrates are not metabolized by infants as fuel but reach the distal part of the gut intact, where they serve as host defense and prebiotic agents, influencing gut microbial colonization patterns (Bode, 2015).

Essential Fatty Acids

The essential fatty acids, linoleic and linolenic acids, are present in ample quantities in human milk and commercial formula.

Without an adequate intake of these fatty acids, essential fatty acid deficiency (thrombocytopenia, dermatitis, increased infections, and delayed growth) can develop in as little as 1 week. Only 0.5 g/kg per day of essential fatty acids (~4% of total energy intake) will prevent the deficiency. α -Linolenic acid is an important precursor for synthesis of both eicosapentaenoic acid and docosahexaenoic acid (DHA). The very long chain polyunsaturated fatty acids arachidonic acid (AA) (20:4 ω -6) and DHA (22:6 ω -3) are found in human milk but not bovine milk and are components of phospholipids found in brain, retina, and red blood cell membranes. AA and DHA functionally have been associated with body growth, vision, and cognition. In addition, the fatty acids are integral parts of prostaglandin metabolism. When their diet was supplemented with polyunsaturated fatty acids, formula-fed premature infants had red blood cell concentrations of DHA paralleling those of similar infants fed human milk. Follow-up studies of such supplemented infants suggest improvements in visual acuity compared with infants that received no supplementation but of similar magnitude to that in infants fed human milk (Carlson et al., 1996). Improvement in cognitive measures during the first year of life has also been shown. Both AA and DHA are now added to premature formula. The recommended intakes for DHA and AA are 11–27 mg/100 kcal and 16–39 mg/100 kcal, respectively (Agostoni et al., 2010; Lapillonne et al., 2013; Uauy and Mena, 2015).

Carnitine

Carnitine is synthesized from lysine and methionine and serves as an important effector of fatty acid oxidation in the mitochondria. The provision of carnitine in the diet results in improved fatty acid oxidation. Human milk contains abundant carnitine, and all infant formulas are supplemented with carnitine.

Human Milk Enzymes

Human milk contains enzymes that aid the infant in nutrient digestion. α -Amylase, the enzyme responsible for most of polysaccharide digestion, is not fully developed at birth even in term infants, who have only 0.2%–0.5% of adult activity. Mammary amylase is active at the pH of both the stomach (3.5) and the duodenum (5.3) and can aid the deficient infant in the digestion of glucose polymers and starches. Although human milk does not contain substrate for α -amylase, this enzyme may aid in digestion of feedings, including infant formula or HMFs that contain complex carbohydrates. Lipases (similar to pancreatic lipase) are present in human milk and aid in digestion of triglycerides such that a significant fraction are broken down into free fatty acids and glycerol before digestion in the small intestine. Bile salt-stimulated lipase, a lipase present in human milk, is highly active because of its wide substrate specificity: it hydrolyzes monoacylglycerols, diacylglycerols, and triacylglycerols, as well as cholesterol esters. This enzyme is also stable in the duodenum and resistant to the low pH of the stomach (Lonnerdal, 2003).

Vitamins and Minerals

The vitamin and mineral content of preterm human milk, as well as currently available multicomponent human milk fortifiers, are shown in Table 68.3.

Donor Human Milk

Recent recommendations have been published by the European Society for Paediatric Gastroenterology, Hepatology and Nutrition, the AAP Section on Breastfeeding, and the WHO endorsing the

HMF, Human milk fortifier; IU, international unit; NA, not available; PTHM, preterm human milk.

use of donor human milk in preterm infants when maternal milk is unavailable, either as a sole diet or as a supplement to maternal milk (World Health Organization, 2011; Section on Breastfeeding, 2012; ESPGHAN Committee on Nutrition et al., 2013). Despite these recommendations and widespread use, large-scale studies of the use of donor human milk in VBLW infants during the era of routine human milk fortification are lacking. In 2011 the US Surgeon General called for further research to identify areas where the evidence regarding donor milk is inconclusive and to develop evidence-based clinical guidelines for its use (US Department of Human & Health Services, 2014).

Most donor human milk currently used in NICUs in North America is dispensed from the 26 member banks of the nonprofit Human Milk Banking Association of North America (HMBANA), which collectively dispensed 4.2 million ounces of milk in 2015. The rapid rise in donor milk use is apparent when one considers that in 2007 HMBANA dispensed 1 million ounces of milk, demonstrating that demand increased fourfold in 8 years. Milk processed and dispensed by HMBANA is obtained from healthy donors, most of whom delivered term infants and who undergo extensive behavioral and serologic screening (Human Milk Banking Association of North America, 2015). Donors are screened for human immunodeficiency virus, human T-lymphotropic virus1, human T-lymphotropic virus2, hepatitis B, hepatitis C, and syphilis. Testing may be performed via antibody screening or nucleic acid polymerase chain reaction as desired by each bank. Milk is processed by the pooling of donations from 3–10 donors and pasteurization of the milk by heating it to 62°C for 30 min (Holder pasteurization). After pasteurization a sample of milk from each pool is sent for bacteriologic screening. HMBANA member banks maintain records allowing donors and recipients to be matched. Smaller contributions to the volume of donor milk used in US NICUs are made by two commercial producers, Prolacta Bioscience (City of Industry, California) and Medolac Laboratories (Lake Oswego, Oregon). These companies use proprietary processes for pasteurization and donor screening.

Differences Between Maternal and Donor Human Milk

Donor human milk and maternal milk differ in some important aspects, and these differences must be kept in mind when one is choosing donor milk as a diet for preterm infants. Since donor human milk is obtained primarily from mothers who delivered term infants, this milk is lower in protein than preterm maternal milk. Calculations of protein and energy intakes in preterm infants are often conducted with an estimate of 1.4 g/dL for protein content. Donor milk, however, typically contains less protein than this, with studies reporting values of 0.9–1.1 g/dL, with more than 30% of samples in one study of 273 donors having a protein content of less than 1 g/dL (Wojcik et al., 2009). In addition to most donor milk being term human milk, the handling needed to process and feed donor milk causes additional nutrient loss, with 9% protein loss and 13% fat loss between raw milk and milk that has been pasteurized and subjected to a sham nasogastric bolus tube feeding (Vieira et al., 2011). Fat content of donor human milk is similar to that of maternal milk, with less variability per batch of HMBANA donor milk than individual expression of maternal milk because of the pooling process. Some HMBANA milk banks collect and pool milk from mothers who deliver preterm and dispense it after pasteurization as preterm milk to provide higher protein content for preterm infants. Additionally, some HMBANA milk banks analyze the nutrient content of their pooled milk, labeling containers with energy (kcal/dL) and/or protein (g/dL) content, although this practice is neither universal nor mandated

by HMBANA. Prolacta Bioscience and Medolac Laboratories both label their commercial products with nutrient content.

In addition to the nutritional differences noted earlier, some of the unique host defense mechanisms present in human milk are inactivated by Holder pasteurization and freezing. Forty percent to 60% of the sIgA and 60% of the lactoferrin in human milk are inactivated by Holder pasteurization, as are all live white blood cells. Lysozyme and oligosaccharides, other antiinfective protective factors in human milk, are unaffected. There are no published data regarding the effects of the proprietary pasteurization processes used by Prolacta Bioscience and Medolac Laboratories on host defense compounds in donor human milk. Bile salt–stimulated lipase and amylase are also inactivated by Holder pasteurization.

Initiation, Mode, and Advancement of Enteral Feedings

The initiation, mode, and rate of advancement of enteral feeding all remain a topic of controversy in neonatology. The literature does not definitively inform practice, resulting in substantial variation among NICUs. The main concern regarding enteral feeding is the presumed association of enteral feeding and NEC, with early initiation and/or rapidly advancing feeding perceived to increase the risk of this complication of prematurity.

Current practice favors early minimal enteral feeding, also referred to as *trophic feeding* or *GI priming*, as lack of enteral feeding has been shown to delay gut maturation in preterm infants and results in negative effects. Fasting results in intestinal atrophy, diminished intestinal weight and size (in animal models), delayed maturation of intestinal enzyme function, increase in gut permeability and bacterial translocation, and delay in maturation of the intestinal motor function. Additionally, delay in enteral feeding can extend the duration of parenteral nutrition, with its well-described risks, including metabolic disturbance, direct hyperbilirubinemia and cholestasis, and late-onset sepsis.

Several Cochrane reviews, published since 2013, have investigated various aspects of feeding initiation and advancement in preterm infants (Table 68.4), with underwhelming results. These issues have been difficult to study in a rigorous manner but have been addressed in a series of Cochrane systematic reviews (Kennedy et al., 2000; Tyson, Kennedy, 2000). The primary goal is to determine the optimal feeding regimen that does not increase the incidence of NEC. Comparisons of (1) early (<4 days of age) trophic versus delayed initiation of feeding, (2) early (<4 days) versus delayed progressive feeding advancement, and (3) slow (<24 mL/kg per day) versus faster feeding volume advancement yielded no association between any of these interventions and the incidence of NEC. Early progressive feeding was associated with a 2-day shorter hospital stay, and slow feeding volume advancement was associated with increased risk of invasive infection, not including NEC. The authors of all these metaanalyses concluded that early trophic feeding, early progressive feeding, and faster feeding volume advancement are not associated with increased risk of NEC, but that evidence for benefit or harm from any of these feeding techniques is not available. They urge caution in interpretation of studies and recommend further randomized trials (Morgan et al., 2013, 2014, 2015).

Tube Feeding

Preterm infants are often unable to feed by mouth at the breast or via a bottle at birth because of developmental immaturity. A

TABLE 68.4 Evidence for Early Trophic Feeding, Delayed Progressive Feeding, and Slow Advancement of Feeding Volumes in Very Low Birth Weight Infants: Metaanalyses

| Metaanalysis | Primary Comparison | Population | Results |
|----------------------|--|--|---|
| Morgan et al. (2013) | Trophic feeding at <4 days of age for at least 7 days vs enteral fasting | Nine trials 754 VLBW or very preterm infants | No difference in days to full feeds (MD -1.05, 95% CI -2.61 to 0.51), risk of NEC (RR 1.07, 95% CI 0.67 to 1.70) |
| Morgan et al. (2014) | Delayed (>4 days) progressive feeding vs early (<4 days) feeding | Nine trials 1106 infants, few <28 weeks or <1000 g | Decreased length of stay for the early feeding group (MD 2.11 days, 95% CI 0.31 to 3.9, $P = .02$) No difference in risk of NEC (RR 0.93, 95% CI 0.64 to 1.34), mortality (RR 1.18, 95% CI 0.75 to 1.88) |
| Morgan et al. (2015) | Slow (<24 mL/kg per day) vs faster advancement of feeding | Nine trials 949 infants, most 1000 to 1500 g at birth | Higher incidence of invasive infection in the slow advancement group (RR 1.46, 95% CI 1.03 to 2.06, $P = .03$) No difference in risk of NEC (RR 1.02, 95% CI 0.64 to 1.62), mortality (RR 1.18, 95% CI 0.9 to 1.53) |

CI, Confidence interval; MD, mean difference; NEC, necrotizing enterocolitis; RR, risk ratio; VLBW, very low birth weight.

metaanalysis of small studies suggested that infants with postmenstrual age as low as 28 weeks could safely be exposed to breastfeeding (Lucas and Smith, 2015) and that introduction of oral feeding can be accomplished at 30 to 31 weeks' postmenstrual age (Simpson et al., 2002). However, extremely preterm infants may be unable to even begin oral feeding attempts for many weeks after birth and thus are dependent on NG or OG tube feeding. NG/OG feedings may be administered via a timed infusion, with use of an electronic pump, or via gravity bolus. Timed infusions can be periodic, occurring at a specified interval and lasting a specific duration, with a period of rest between feedings, or continuous, in which milk is infused slowly 24 hours a day with no rest period. There are theoretical benefits and risks from both methods of feeding, although research is sparse, with small trials. Continuous feedings may improve energy absorption while decreasing energy expenditure when compared with bolus feedings (Grant, Denne, 1991), improve growth, and reduce feeding intolerance (Toce et al., 1987). Conversely, continuous feeding may disrupt normal cyclical patterns of GI hormone release stimulated by intermittent feeding (Aynsley-Green et al., 1982). Bolus feeding promotes the normal physiologic surge of GI hormones, which may enhance maturation of the preterm GI tract (Aynsley-Green et al., 1990), but immature GI function, including delayed gastric emptying and abnormal intestinal motility, may result in feeding intolerance. With both tube feeding methods, nutrient delivery can be impaired by losses of nutrients that remain in feeding tubes and infusion systems rather than reaching the infant. Fat, particularly, is known to adhere to feeding equipment, decreasing energy delivery (Rayyan et al., 2015). When gravity bolus, 30-min pump infusion, and continuous infusion were compared with simulated feeding techniques using fortified human milk, the least amount of fat was lost with gravity bolus (6%), and the greatest amount was lost with continuous infusion (25%) (Rogers et al., 2010).

Human Milk Fortification

Although human milk is the appropriate and preferred diet for preterm infants, these infants are at risk of growth failure if unadulterated milk is used. VLBW (<1500 g) infants, particularly those born early in the third trimester of pregnancy, have much higher calorie, protein, and mineral needs than term infants because of the rapid growth and development that occurs at the end of

pregnancy. Therefore it is standard practice to add multicomponent HMF to human milk fed to VLBW infants to provide adequate nutrients (primarily protein and minerals) to support growth. Fortification is initiated when infants are tolerating a significant volume of human milk intake, typically between 50 and 120 mL/kg per day, and the timing is highly variable by NICU, with no evidence to support any specific target volume for initiation. HMFs are typically produced from bovine milk and contain standard doses of hydrolyzed or intact protein, as well as carbohydrate, fat, electrolytes, minerals, and vitamins. There is also a HMF available that is made from donor human milk. The nutrient, vitamin, and mineral contents of the three most commonly used HMFs in the United States in 2016 are reported in Table 68.3 as an example. Bovine fortifiers are available in both liquid and powder form, although liquid form is preferred for NICU use because of safety concerns regarding the sterility of powder products. Human milk-derived HMF is a liquid product. Although when used according to manufacturer directions all products result in fortified milk containing approximately 24 kcal/oz, protein content differs substantially, which clinicians must be aware of when managing growth in VLBW infants who have high protein requirements.

The recommended target enteral protein intake to achieve growth in this population is 3.5–4.5 g/kg per day with energy of 120–130 kcal/kg per day. When HMF is added to preterm human milk (with protein content assumed to be at least 1.4 g/dL), all three current products achieve appropriate protein intake (3.9–5.4 g/kg per day). However, if the protein content of the base milk is lower, such as in donor human milk from term donors or maternal milk after the first 3 weeks of life, protein intake may be insufficient. Thus the step of adding standard amounts of HMF according to manufacturer directions may not be sufficient; growth must be monitored with additional fortification provided as necessary.

Standard Fortification

The process described earlier is referred to as *standard fortification*, wherein a standard composition of human milk is assumed, and protein and energy intakes are estimated with these values. Growth is monitored, and if it is insufficient, additional products are added to increase the estimated protein and/or energy content of the milk, with use of additional HMFs (bovine or human derived) or single-component protein, carbohydrate, or fat supplements. These interventions are driven solely by infant growth response to feeding.

Because of unknown and certain variability in human milk nutrient content, standard fortification is imprecise but has been shown to be successful in achieving growth in some studies using both bovine (Colaizy et al., 2012) and human milk–derived HMF (Hair et al., 2013).

Adjustable Fortification

Adjustable fortification is a modification of standard fortification in which infant blood urea nitrogen (BUN) level is monitored as a biochemical marker for adequate protein intake. When the weekly obtained BUN level is lower than the desired range (9–14 mg/dL) (Alan et al., 2013), additional protein is added until BUN reaches the target level. In one small study, use of this fortification technique resulted in improved weight and head circumference growth, as well as higher Bayley Scales of Infant and Toddler Development scores at 18 months compared with the use of standard fortification (Ergenekon et al., 2013).

Target (or Individualized) Fortification

Both standard and adjustable fortification are imprecise, in that nutrient content of the human milk used is estimated with the use of standard assumptions, which are certainly not accurate in every case. The technique of target fortification accounts for the variability in protein, energy, fat, and carbohydrate content in human milk by measuring these nutrients directly through regular milk analysis using near-infrared or mid-infrared analysis instruments. Specific doses of fortifier, either single component or multicomponent, are added to bring the nutrient content of the milk to the desired targets. This approach when used to determine energy density of human milk, with supplementation of the milk with a human milk cream product when the energy density was less than 20 kcal/oz, resulted in superior weight and length gain compared with weight and length gain in a control cohort of infants treated with standard fortification and no milk analysis (Hair et al., 2014). Another group of investigators used this approach to determine fat, protein, and carbohydrate content of 12-hour pools of maternal milk and fortified each macronutrient to target levels. They found this approach resulted in appropriate weight gain and to be clinically feasible (Rochow et al., 2013).

Infant Nutrition and Growth

A growing body of literature suggests that early nutrition has long-term implications for health and development of all infants and particularly preterm infants. In most scenarios the primary goal of postnatal nutrition for the preterm infant is to match as closely as possible expected in utero growth and development. Ideally this would also optimize long-term developmental outcomes. However, feeding the preterm infant is associated with several challenges. Physiologic weight loss in the first few days after birth sets preterm infants up for “catch-up growth,” and it is extremely difficult to provide nutrition (and minerals, in particular) at a rate that matches in utero accretion rates. On the other hand, potential risks of overnutrition may include short-term risk such as increased rates of NEC and longer-term risks such as metabolic syndrome. Most data supporting current nutritional practice in this population are derived from observational studies. The inherent limitations of this type of study design influence the conclusions that can be drawn about the links between nutrition, morbidities, growth, and outcomes.

After birth, preterm infants may lose up to 15%–20% of their birth weight and then regain their birth weight by about 2 weeks

of life. After this physiologic weight loss and regain of birth weight, VLBW infants often gain weight at approximated intrauterine rates. However, the impact of poor growth during the first few weeks persists. By term-corrected age, most preterm infants remain far below the reference weight of an infant born at the same postmenstrual age (Ehrenkranz et al., 1999).

Postnatal growth failure in the preterm infant, defined as body weight or length below the 10th percentile of expected intrauterine growth at the time of hospital discharge, is extremely common. The rates of reported growth failure depend on the population studied and generally increase with decreasing gestational age and birth weight and increase with the severity of illness. Among more than 24,000 infants in the Pediatrix Medical Group, Inc. database who were born before 34 weeks gestation, 28% had weight below the 10th percentile at discharge (Clark et al., 2003). Early postnatal growth failure may increase the risk of long-term adverse effects, such as cardiovascular disease and adult-onset diabetes (De Curtis and Rigo, 2004). Significant variation between hospitals in the degree of postnatal growth failure suggests that this outcome is modifiable and may at least in part reflect differences in nutritional practice (Bloom et al., 2003; Cooke et al., 2004).

Extremely preterm infants with a lower growth trajectory while in the hospital are more likely to have weight, length, and head circumference below the 10th percentile at 18 months’ corrected age (Ehrenkranz et al., 2006). Both in the United States and in other countries, infants born preterm have growth failure at least into adolescence and likely beyond (Ford et al., 2000). The most extremely preterm infants remain smallest and in particular may have the smallest head circumferences throughout childhood (Ericson and Kallen, 1998).

Longitudinal growth is slower in infants with morbidities of prematurity (Ehrenkranz et al., 1999; Clark et al., 2003). On the other hand, infants with morbidities such as lung disease or NEC may be fed less aggressively because of their underlying illness (Ehrenkranz et al., 2011). Infants with morbidities of prematurity continue to experience poor growth through at least 2 years, which is only in part explained by the lower growth velocity during the first several months of life (Bertino et al., 2007; Ramel et al., 2012).

Extrauterine growth failure among preterm infants has been a target of multiple randomized trials and nutritional interventions in the past several decades. These have led to the current “aggressive” approach to nutrition for very preterm infants, including institution of intravenous protein supplementation of 3.5g/kg per day at birth or as soon as possible within the first day of life, trophic enteral feeding—ideally with expressed maternal milk—as soon as possible, and early fortification of both human milk and preterm formula feedings (Ehrenkranz, 2007). This approach improves energy and nitrogen balance, promotes earlier regain of birth weight, and does not increase the risk of acidosis, NEC, sepsis, or other adverse clinical outcomes. Several studies suggest that lean growth and early catch up are optimized with a high-protein regimen. In ELBW infants, early enteral provision of protein significantly increases weight, length, and head circumference at least until 36 weeks’ postmenstrual age (Poindexter et al., 2006). Shorter duration of dependence on parenteral nutrition is associated with improved longitudinal growth. Nevertheless, “normal” immediate postnatal weight loss is augmented by a suboptimal nutritional state during the first several weeks of life, and growth failure remains common. An observational study demonstrated that postnatal weight loss can be limited to the first few days (and limited to ~8% of birth weight) with optimized early parenteral and enteral

nutrition, including a goal of achieving 120 kcal/kg per day and 3.8 g/kg per day of protein by the end of the first week (Senterre, 2011).

Infants with intrauterine growth restriction (IUGR) likely have different metabolic programming and therefore different nutritional requirements from appropriately grown infants. Term infants born with IUGR have higher rates of adult-onset disease, including hypertension, heart disease, and diabetes, and early death (Barker, 1990; Phenekos, 2001). Unfortunately, similar data on IUGR preterm infants are not available. Little is known about how to identify or select these infants, and no studies have specifically targeted the nutritional needs of this population. Therefore the nutrition and growth targets of the IUGR preterm infants are currently similar to those of the appropriate for gestational age preterm infant. The risks of slow growth and persistent small size for age, which are common in the IUGR population, likely outweigh the risks associated with rapid early catch-up growth. Ultimately, adult weight and risk of long-term metabolic consequences are more likely to be related to parental weight, adult weight, and lifestyle choices than to aggressive early nutrition (Greer, 2007) in the IUGR infant.

While growth failure in the preterm or IUGR infant remains a significant concern, growth that is too rapid in infancy is also associated with adult-onset diseases, including obesity. This phenomenon, in which early “programming” leads to future adverse effects, is commonly termed the *Barker hypothesis* (Barker et al., 1993). Large term infants are more likely to be overweight as adults (Stettler, Iotova, 2010). In a multicenter study of more than 19,000 term-born American children, growth in the first 4 months was associated with risk of overweight at 7 years (Stettler et al., 2002). However, it is unlikely that these studies of term infants apply to preterm infants, in whom the benefits of brisk early growth may outweigh any potential risks. There is little evidence that current attempts to maximize growth in the NICU “programs” very preterm or critically ill infants for later adverse metabolic consequences. In fact, accelerated or catch-up growth in preterm infants may be associated with improved outcomes.

Assessing Growth and Body Composition in Infants

Infant growth is generally assessed by anthropometry, in which body weight, length, and head circumference are measured. These are compared with established reference data or plotted on a set of growth curves. In general, growth curves for preterm infants are based on expected intrauterine growth. Others are based on postnatal growth data. Several sets of curves have been established for preterm infants; differences are related to population characteristics and sample size, as well as neonatal nutrition practices. In general, curves for both male and female infants allow the clinician to assess growth parameters relative to gestational age and sex-matched norms. Importantly, preterm infants do not always have proportional growth—or proportional growth failure—in the NICU. Linear growth often falters more than weight and may take longer to recover (Ramel et al., 2012).

Olsen et al. (2015) published body mass index (BMI) curves for preterm infants. BMI curves allow the clinician to assess the proportion of weight to length and to distinguish proportionate from disproportionate growth, most commonly when weight increases faster than length. Similarly to other growth and body composition parameters, BMI varies with sex and gestational age.

While a preterm infant is hospitalized, growth should be monitored serially and plotted on a set of standardized growth curves. These curves should include weight, length, head circumferences, and possibly BMI. Nutrition should be adjusted to target expected intrauterine growth, which is about 20 g/kg per day for the smallest infants (Ziegler et al., 2002).

Changes in body composition over the first months and years of life are associated with nutritional programming of adult morbidities. Assessment of anthropomorphic measures, including BMI, does not inform the clinician about the relative contributions of bone mass, fat mass, and lean mass to body size. Data on the contributions of bone, fat, and lean mass may better reflect the nutritional state of an infant and could potentially inform decisions about appropriate provision of nutrients and goals for growth.

Many preterm infants have poor growth into adolescence, with lower BMI and lower body weight. They have equal fat mass and waist circumference, with an increase in relative abdominal adiposity compared with term-born children. Adiposity may also differ in different groups of preterm infants. For instance, small for gestational age preterm infants have lower fat mass between term-corrected age and 3 months of life but catch up after that point to match appropriate for gestational age born preterm infants (Roggero et al., 2007). Critically ill preterm infants may have increased central or abdominal adiposity, which is a marker of insulin resistance, versus subcutaneous adiposity. This has unclear implications for short-term and long-term health. Increased abdominal adiposity, rather rapid increases in body weight or the absolute body weight itself, may be the factor that puts some preterm infants at increased risk of adult-onset diseases (Fewtrell et al., 2004; Uthaya, 2005).

Little else is known about the changes in body composition in preterm infants and how to distinguish “normal” from “abnormal.” Yet, an understanding of body composition is essential for comparing quality versus quantity of weight gain. An appropriate technique for assessment of body composition must be standardized, valid, reliable, portable, inexpensive, and noninvasive. Ideally, such technology would be used serially to assess response to interventions (Roggero et al., 2007). Several techniques for assessment of body composition, including dual-energy X-ray absorptiometry and magnetic resonance imaging, are available for research use but cannot practicably be applied in clinical settings, particularly in critically ill neonates. Until additional data on “normal” trajectories of body composition in preterm infants and appropriate technologies for assessment of body composition exist, body composition cannot be used to guide nutrition interventions in the NICU.

Growth and Developmental Outcomes in Preterm Infants

Optimal nutrition is not only essential to match appropriate growth trajectories and minimize risk for adult-onset diseases. Early growth and nutrition impact developmental outcomes throughout childhood. The most likely explanation for this long-term impact of infant nutrition is that the first year of life represents a “critical window” of brain growth. In a multicenter cohort study, Ehrenkranz et al. (2006) divided ELBW infants into quartiles of in-hospital growth velocity rates. They identified correlations between the quartile of in-hospital growth velocity and the risk of cerebral palsy and developmental outcomes more than two standard deviations below the mean at 18–22 months’ corrected age. These relationships persisted when they were adjusted for multiple potential confounders, such as center and severity of illness.

Postdischarge growth is likely at least as important for developmental outcomes as in-hospital growth. Preterm infants who experience catch-up growth by 8 months' corrected age have better developmental outcomes than those who do not catch up or fail to thrive by 8 months (Hack et al., 1982). By 8–9 years' corrected age, head growth less than 2 standard deviations below the mean for age at 8 months' corrected age is independently associated with lower intelligence quotient and lower reading, mathematics, spelling, and language scores (Hack et al., 1991). In a cohort of 62 VLBW infants followed up prospectively until 24 months' corrected age, poor linear growth velocity in this period was associated with lower cognitive performance at 24 months (Ramel et al., 2012).

It remains unknown which specific nutritional interventions in hospital and after discharge would optimize both growth and developmental outcomes in the preterm infant. For example, although parenteral provision of amino acids before as compared with after 5 days of life improves in-hospital growth in ELBW infants, it does not seem to improve developmental outcomes at 18 months' corrected age (Poindexter et al., 2006). In two randomized trials of fortified versus term formula at discharge for preterm infants, infants fed fortified preterm formula had improved growth at 18 months (Lucas et al., 2001). However, there was no difference in developmental scores at 18 months in either trial.

Continued research will be essential to establish which growth targets are associated with the best long-term developmental and health outcomes in preterm infants and which nutritional strategies best achieve these targets.

Postdischarge Nutrition for the Premature Infant

When preterm infants are discharged, they have accumulated energy, protein, and mineral deficits. In addition, they are generally discharged before their original anticipated birth date. Together, these factors lead the preterm infant to have higher nutritional needs after discharge than healthy appropriate for gestational age term infants. Targeting of an appropriate trajectory is essential because postnatal growth through age 1 year in infants born before 32 weeks has a positive relationship with height, weight, and BMI until at least 19 years (Euser et al., 2005).

At least one small, randomized trial (Koo and Hockman, 2006) has demonstrated improved growth among preterm infants fed standard, rather than fortified, formula after discharge. On the other hand, several randomized trials have demonstrated improved growth and mineral accretion among both well former preterm infants and infants with BPD when fed fortified formula feedings after discharge (Brunton et al., 1998; Lucas et al., 2001). Carver et al. (2001) performed a small trial in which infants with birth weights less than 1800 g were randomized to receive term formula or a nutrient-enriched (22 kcal/oz) formula until 12 months' corrected age. High rates of loss to follow-up limit the conclusions that can be drawn from this trial. However, infants who received the nutrient-enriched formula seemed to have improved proportional growth, because they weighed more at 6 and 12 months' corrected age, were longer at 6 months' corrected age, and had better head circumference growth at term and at 1, 2, 6, and 12 months' corrected age. The nutrient-enriched formula may have been particularly beneficial among infants with birth weight less than 1250 g. Bishop et al. (1993) found increased bone mineral content up to 9 months' corrected age in infants who received nutrient-enriched formula compared with term formula.

Fewer data are available to support decisions about fortification of maternal milk after discharge of the preterm infant, particularly when families express a goal of nursing rather than bottlefeeding their infants. Infants fed unfortified maternal milk have slower growth and lower bone mass than those fed formula after discharge. Fortification of maternal milk is most commonly accomplished by addition of a postdischarge formula to maternal milk to increase energy, protein, calcium, and phosphorus intake. Such fortification improves mineral accretion but may not impact growth in the long term. Nevertheless, on the basis of the existing literature, "fortified" or high-calorie/high-protein milk feeding has become the standard for the preterm infant at discharge, whether feeding is with human milk or formula. Fortification should be continued until at least 6 months' corrected age to optimize catch-up growth. After that time, overly aggressive nutrition may carry an increased risk of adult-onset disease (De Curtis and Rigo, 2004).

Postdischarge formulas supply more energy (22 kcal/oz), protein (2.8 g/100 kcal), calcium, phosphorus, and zinc than term formulas. Compared with term formula, these formulas provide 49% more protein, 10% more calories, 48% more calcium, 62% more phosphorus, and 75% more zinc. Even at intake volumes of up to 200 mL/kg per day, neither maternal milk nor preterm formulas contain the recommended allowance of vitamin D (Greer, 2007). Thus vitamin D should be provided as a supplement to all infants both during the hospitalization and after discharge. In infants younger than 1 year, 1 L of vitamin D–fortified infant formula or cow's milk per day will provide sufficient vitamin D to discontinue supplementation.

Postdischarge nutrition should be discussed during the discharge planning process with the families of premature infants. In addition, these plans should be discussed with the primary medical caregiver to ensure a smooth transition to the outpatient setting. Premature infants who are formula fed should be fed nutrient-enriched postdischarge formula for the first year of life. The duration of use will differ depending on the severity of postnatal growth failure, bone health, and proportional growth after NICU discharge. Likewise, growth of premature infants who on discharge are receiving human milk should be closely monitored to ensure optimal proportional growth.

Parenteral Nutrition for the High-Risk Neonate

SCOTT C. DENNE

KEY POINTS

- A high proportion of extremely low birth weight (ELBW) infants experience poor growth in the neonatal intensive care unit. Nutritional deficits that rapidly accumulate shortly after birth are a major factor in these growth outcomes.
- Nutritional deficits can be minimized and growth outcomes improved by beginning parenteral nutrition soon after birth. Initial support should include glucose at 4–7 mg/kg per min, amino acids at 2–3 g/kg per day, and lipids at 2 g/kg per day.
- Goals for full parenteral nutrition support in ELBW infants are 90–100 kcal/kg per day (13–15 g/kg per day glucose, 3–4 g/kg per day lipid, 3.5–4.0 g/kg per day amino acids).
- There is increasing attention to fish oil–based lipid solutions, which appear to ameliorate parenteral nutrition–associated liver disease in infants that require long-term intravenous nutrition. These products are currently not commercially available in the United States. Randomized trials evaluating fish oil–based and other new parenteral nutrition solutions in preterm infants are greatly needed.

Effective nutritional support of premature and critically ill infants is largely dependent on parenteral nutrition, especially in early postnatal life. In practice, the supply of nutrients to preterm neonates—especially extremely low birth weight (ELBW) infants—is often inadequate, and these infants accumulate major deficits in early postnatal life (Berry et al., 1997; Embleton et al., 2001; Olsen et al., 2002). A high proportion of ELBW infants exhibit poor growth in the neonatal intensive care unit (NICU), with those at the lowest gestational age and birth-weight at greatest risk (Clark et al., 2003; Fanaroff et al., 2007). However, growing evidence indicates that early use of parenteral nutrition may minimize protein losses and improve growth outcomes (Wilson et al., 1997; Thureen et al., 2003; Poindexter, 2005; Stephens et al., 2009). For example, Wilson et al. (1997), in a randomized clinical trial in 125 sick very low birth weight (VLBW) infants, demonstrated that early aggressive parenteral nutrition combined with early enteral feeding reduced growth failure without an increased incidence of adverse clinical consequences or metabolic derangements. Multiple observational studies have produced similar results (Poindexter, 2005; Valentine et al., 2009; Cormack et al., 2013; Rigo and Senterre, 2013; Bolisetty et al., 2014; Morgan et al., 2014). In addition to

improved growth outcomes, Stephens et al. (2009) found an association between increased protein and energy intake in the first week of life and higher Bayley Mental Development Index scores at 18 months' corrected age. Parenteral nutrition solutions, although still imperfect, have improved markedly from the early days of use, and complications are less common. At present, however, improved growth outcomes in preterm infants continue to require a consistent effort at providing parenteral nutritional support, especially in early postnatal life. This means initiating parenteral nutrition within the first 24 hours, continuing until enteral nutrition supplies at least 75% of the total protein and energy requirements, and reinstituting parenteral nutrition quickly whenever enteral feeding is suspended.

Components of Parenteral Nutrition

Protein

The initial goal of parenteral nutrition is to minimize losses and preserve existing body stores; this is particularly important for protein. Protein losses are significant in all neonates in the absence of amino acid intake, and these losses are the highest in the most immature neonates. For example, 26-week-gestation infants lose 1.5 g/kg per day of body protein; protein losses in term infants are approximately half that rate (0.7 g/kg per day) (Denne et al., 1996). These high rates of loss in extremely premature infants result in substantial protein deficits. If extremely premature infants are provided with no amino acid supply, they lose over 1.5% of their body protein per day when they should be accumulating protein at a rate of 2% per day. After only 3 days of no protein intake, a 10% protein deficit results.

Fortunately, there is good evidence that early amino acid intake can compensate for high rates of protein loss and thus preserve body protein, even at low caloric intakes (Saini et al., 1989; Van Lingen et al., 1992; Rivera et al., 1993; Kashyap and Heird, 1994). Amino acid intakes of 1.1–2.3 g/kg per day at caloric intakes of 30–50 kcal/kg per day change the protein balance from significantly negative to neutral or positive in sick VLBW infants (Saini et al., 1989; Van Lingen et al., 1992; Rivera et al., 1993). In addition, Thureen et al. (1998) conducted a randomized trial of 1 g/kg per day versus 3 g/kg per day amino acid intake immediately after birth in extremely premature infants. Despite a modest caloric intake in both groups (approximately 50 kcal/kg per day), protein

accretion was significantly greater in the higher amino acid intake group. In all these studies evaluating the effect of early amino acid intake in premature infants, no differences in ammonia concentrations or acid–base status were observed between infants who received amino acids and those who did not (Saini et al., 1989; Van Lingen et al., 1992; Rivera et al., 1993; Paisley et al., 2000). In addition, these studies demonstrated no relationship between amino acid intake and blood urea nitrogen (BUN), although other studies reported modestly elevated BUN levels in neonates receiving higher amino acid intakes at 7 days of age (Clark et al., 2007; Blanco et al., 2008). The fact that BUN concentrations do not usually correlate with amino acid intake in early postnatal life suggests these levels are related primarily to fluid status and that increased BUN levels should not be used as an indication of protein excess. These data indicate that providing parenteral amino acids at a rate of 2–3 g/kg per day as soon as possible after birth (within hours) can preserve limited body protein stores in sick premature and ELBW infants, even at low caloric intakes.

It is important to point out that even though parenteral amino acid administration is beneficial at low caloric intakes, increasing caloric intake is likely to improve protein accretion. Older studies in premature infants have suggested that increasing caloric intake from 50–80 kcal/kg per day can significantly improve protein balance (Pineault et al., 1988). Based on currently available data, 70–80 kcal/kg per day may be sufficient to maximize protein accretion. However, additional energy beyond this amount probably is necessary to produce appropriate fat accretion (see “Energy” section later).

The ultimate goal of parenteral amino acid administration is to achieve the rate of fetal protein accretion. Based on a variety of studies measuring protein losses and balance, 3.5–4.0 g/kg per day of amino acids is a reasonable estimate of parenteral protein requirements in ELBW infants (Ziegler, 2007) (Table 69.1). Some evidence suggests that up to 4.0 g/kg per day of

amino acids is well tolerated by ELBW infants (Porcelli and Sisk, 2002). For premature infants with birthweights over 1000 g, estimated parenteral protein requirements are 3.0–3.5 g/kg per day. Estimates for term infants are 2.5–3 g/kg per day. Parenteral protein intake recommendations for premature infants are shown in Table 69.1.

The composition of currently available amino acid solutions is shown in Table 69.2. These amino acid solutions were designed to mimic plasma amino acid concentrations in healthy 30-day-old breastfed term infants (TrophAmine, B. Braun Medical Inc.) or fetal or neonatal cord blood amino acid concentrations (Primene, Baxter Corporation). No convincing information exists to support the superiority of one neonatal amino acid solution over another.

Although the current neonatal amino acid solutions represent a substantial advance over previous casein hydrolysates and early crystalline amino acid mixtures, these solutions do not contain all the amino acids. Glutamine, an amino acid abundantly supplied by breast milk and potentially conditionally essential in premature infants, is not included in any available amino acid solution because of issues of stability. However, the National Institute of Child Health and Human Development Neonatal Research Network conducted a multicenter randomized clinical trial of parenteral glutamine supplementation and found that parenteral glutamine supplementation did not decrease mortality or the incidence of late-onset sepsis in ELBW infants (Poindexter et al., 2004). In addition, glutamine had no effect on enteral feeding tolerance, incidence of necrotizing enterocolitis, or growth. Tyrosine has very limited solubility, so little is included in current amino acid solutions. TrophAmine contains a soluble derivative of tyrosine (*N*-acetyltyrosine), but this derivative appears to have poor bioavailability. A variety of studies in premature infants suggest that the tyrosine supply may not be optimal in current amino acid solutions (Brunton et al., 2000). Cysteine is not included in most amino acid solutions because it is not stable for long periods. However,

TABLE
69.1

Suggested Daily Parenteral Intakes for Extremely Low and Very Low Birth Weight Infants

| Component (units/kg per day) | ELBW | | | VLBW | | |
|---------------------------------|--------------------|-------------------------|---------|--------------------|-------------------------|---------|
| | Day 0 ^a | Transition ^b | Growing | Day 0 ^a | Transition ^b | Growing |

a cysteine hydrochloride supplement that can be added to the parenteral nutrition solution just before delivery is commercially available. There is supporting evidence that when cysteine hydrochloride supplements are added to parenteral nutrition, nitrogen retention is improved in premature infants (Soghier and Brion, 2006). The addition of cysteine hydrochloride also improves the solubility of calcium and phosphorus in parenteral nutrition solutions and also may improve the status of the important antioxidant glutathione. For these reasons, the addition of cysteine hydrochloride (40 mg/g of amino acid, up to a maximum of 120 mg/kg) is recommended. Cysteine hydrochloride can result in metabolic acidosis, but this possibility can be appropriately countered by the use of acetate in the parenteral nutrition solution as a buffer (Peters et al., 1997).

Energy

The initial goal of parenteral nutrition in early postnatal life is to provide sufficient energy intake to at least match rates of energy expenditure, to preserve body energy stores. Measures of energy expenditure in premature infants have ranged between 30 and

70 kcal/kg per day; energy expenditure increases with energy intake and with advancing postnatal age (Bauer et al., 2003a, 2003b; Torine et al., 2007; Weintraub et al., 2009). Energy expenditure also appears to be greater at lower birthweights (Weintraub et al., 2009). An intake of approximately 70 kcal/kg per day is a reasonable clinical goal to achieve neutral or slightly positive energy balance, although because of glucose and lipid intolerance, this intake may not be achievable for a number of days after birth. Nevertheless, maximizing energy intake within the limits of glucose and lipid tolerance can minimize accumulating energy deficits. It is also important to note that common clinical conditions such as sepsis and chronic lung disease can significantly increase energy expenditure, which can further exaggerate energy deficits (Bauer et al., 2003c; Torine et al., 2007).

To support normal rates of growth, a positive energy balance of 20–25 kcal/kg per day must be achieved (Denne, 2001). This requires 90–100 kcal/kg per day for preterm infants with birthweights of less than 1000 g and 100–110 kcal/kg per day for ELBW infants (Table 69.1). A parenteral intake of 80–90 kcal/kg per day is most often sufficient for term infants. Most of the parenteral calories are best supplied by a balanced caloric intake of lipid and glucose. Parenteral energy requirements are less than those required for enteral nutrition because no energy is lost in the stools. Recommendations for parenteral energy intake are shown in Table 69.2.

Glucose

Glucose is typically the first parenteral nutrient provided to the preterm infant, and glucose administration is initiated minutes after birth to maintain glucose homeostasis and preserve endogenous carbohydrate stores. Although the precise definitions of hypoglycemia and hyperglycemia remain a topic of debate, maintaining glucose concentrations of above 40 mg/dL and below 150–200 mg/dL is a reasonable clinical goal (Cornblath et al., 2000). Hypoglycemia is easily avoided in preterm infants by maintaining a constant intravenous (IV) glucose delivery, but hyperglycemia is more often problematic, especially in ELBW infants shortly after birth. Hyperglycemia is very common in this population in early postnatal life, with up to three-quarters of ELBW infants having glucose concentrations exceeding 150 mg/dL and a third of infants frequently having glucose concentrations over 180 mg/dL (Blanco et al., 2006; Beardsall et al., 2008).

Glucose infusion rates of 4–7 mg/kg per minute (70–110 mL/kg per day of 10% dextrose in water [D₁₀W]) are appropriate starting points for most infants. These rates of glucose infusion approximate or slightly exceed the rate of endogenous glucose release from the liver in term and premature infants with birthweights above 1000 g; therefore these rates of glucose infusion serve to preserve the limited carbohydrate stores in these infants. For ELBW infants, a rate of 8–10 mg/kg per minute is required to match endogenous glucose production (Hertz et al., 1993). Unfortunately, many infants will not tolerate this rate of glucose infusion for several days without developing hyperglycemia. Because ELBW infants can have fluid requirements in excess of 100 mL/kg per day, beginning with 5% dextrose may be necessary to maintain glucose infusion rates in the range of 4–7 mg/kg to achieve glucose homeostasis.

A gradual increase in glucose intake over 2–7 days, up to 13–17 g/kg per day, is usually tolerated when the glucose is combined with amino acid intake. An infusion rate of 18 g/kg per day is a reasonable maximum for IV glucose delivery, because

higher rates probably exceed the glucose oxidative capacity (Jones et al., 1993; Chessex et al., 1995). Exceeding glucose oxidative capacity will drive extensive lipogenesis, an energy-expensive process. Supplying appropriate amounts of glucose rarely requires glucose solution concentrations in excess of 12.5%, unless infants are fluid restricted. Recommendations for glucose intake during parenteral nutrition are provided in Table 69.1.

Some ELBW infants have difficulty tolerating even moderate rates of glucose delivery. This problem can usually be overcome by a temporary reduction in the glucose infusion rate. The use of insulin in this situation remains a controversial practice. Collins et al. (1991), in a small randomized controlled trial, demonstrated increased weight gain in infants who received insulin infusions. No differences in head circumference or length were observed between these infants and controls, suggesting that insulin may have produced increases in fat mass but not in lean tissue. Poindexter et al. (1998) evaluated the effect of insulin on protein metabolism using a euglycemic hyperinsulinemic clamp. Insulin infusion resulted in no improvement in protein balance and unexpectedly produced significant lactic acidosis. An international randomized clinical trial was conducted to determine whether early insulin therapy would reduce hyperglycemia and improve outcomes in VLBW infants (Beardsall et al., 2008). The study demonstrated no improvements in mortality, sepsis, growth, intracranial disease, necrotizing enterocolitis, or chronic lung disease and was terminated early because of futility concerns. Although insulin reduced hyperglycemia, it also resulted in increased episodes of hypoglycemia. Further, the mortality at 28 days was higher in the insulin group. Another randomized controlled trial examined the effect of insulin in hyperglycemic VLBW infants who were randomized to receive insulin either when glucose levels exceeded 150 mg/dL or when glucose levels exceeded 180 mg/dL (Alsweliler et al., 2012). The primary outcome of linear growth was significantly reduced in the more aggressive insulin use group, along with a two times greater rate of hypoglycemia. At present, there is no evidence supporting a clinical benefit from routine insulin administration in VLBW infants. Nevertheless, there are rare VLBW infants who remain hyperglycemic despite very low glucose infusion rates; these infants may require exogenous insulin, beginning at 0.05 unit/kg per hour for a short period of time, to produce normoglycemia.

Meeting the goal of 13–17 g/kg per day of IV glucose will result in a caloric intake of 45–60 kcal/kg per day, which is insufficient by itself to meet total energy needs. IV lipids are necessary to supply the rest of the nonprotein calories. A balanced glucose and lipid approach to supplying nonprotein calories has a number of advantages: it better approximates the carbohydrate-to-fat ratio in enteral feedings, it may improve overall protein accretion, and it minimizes overall energy expenditure (Nose et al., 1987; Van Aerde et al., 1989).

Lipids

IV lipids are made up of triglycerides, phospholipids from egg yolk to emulsify, and glycerol, which is added to achieve isotonicity. IV lipid solutions commercially available in the United States are derived from soybean oil (Intralipid, Hospira, Inc.) or a combination of soybean oil and safflower oil (Liposyn II, Baxter Corporation); these solutions contain long-chain triglycerides. Differences in lipid source result in a slightly different fatty acid profile; the compositions of IV lipid solutions are shown in Table 69.3. All available IV lipid products have a fatty acid profile substantially different from that of human milk.

TABLE 69.3

Composition of Parenteral Lipid Emulsions

| | Intralipid 20% | Liposyn II 20% | Omegaven ^a |
|---------------------|----------------|----------------|-----------------------|
| Oil | | | |
| Soybean | 20 | 10 | – |
| Safflower | | 10 | – |
| Fish | – | – | 10 |
| Fats (%) | | | |
| Linoleic | 50 | 65 | 0.1–0.7 |

DHA, Docosahexaenoic acid; EPA, eicosapentaenoic acid.

^aOmegaven is not approved for use in the United States and is only available under experimental or compassionate use protocol. Omegaven is only available as a 10% solution (10 g lipid per 100 mL).

There is increasing attention on fish oil–based lipid solutions, although none of these products are currently available in the United States. A recent systematic review of fish oil–based emulsions concluded that these products are effective in reducing existing parenteral nutrition–associated liver disease (PNALD) but do not seem to prevent PNALD in neonates (Park et al., 2015). Evaluating fish oil–based and other new parenteral lipid solutions is an area of active interest and will require large randomized trials of premature infants.

IV lipid solutions contain lipid particles similar in size to endogenously produced chylomicrons. These particles are hydrolyzed by lipoprotein lipase into free fatty acids. Lipoprotein lipase activity and triglyceride clearance are reduced in preterm infants of less than 28 weeks' gestation (Brans et al., 1990). Although heparin can release lipoprotein lipase from the endothelium into the circulation, at present no evidence exists that this increases lipid utilization in preterm infants (Spear et al., 1988). In the absence of any information demonstrating clinical benefit of heparin administration, the routine addition of heparin in lipid infusions is not recommended.

Linoleic and linolenic acids cannot be endogenously synthesized and therefore are essential fatty acids for humans. Biochemical evidence of essential fatty acid deficiency may be noted in preterm neonates within 72 hours of birth (Foote et al., 1991). Essential fatty acid deficiency can be avoided if 0.5–1.0 g/kg per day of IV lipid is provided. Additional IV lipid beyond these amounts is necessary if the energy requirements of preterm infants are to be met in early postnatal life.

There is good evidence that early administration of IV lipid to preterm infants is safe and well tolerated. Drenckpohl and colleagues demonstrated that beginning 2 g/kg of lipid on day 1 significantly increased the energy intake of VLBW infants, and hypertriglyceridemia occurred in only 15% of infants

(Drenckpohl et al., 2008). A more recent study showed improved nitrogen balance when lipids were begun at 2g/kg on day 1 in VLBW infants (Vlaardingerbroek et al., 2013). A systematic review and metaanalysis of early versus late IV lipid use in premature infants showed no detrimental effects of early lipids on either death, bronchopulmonary dysplasia, or sepsis (Vlaardingerbroek et al., 2012). However, a beneficial effect from early lipids on long-term growth could not be demonstrated.

In view of the available data, beginning 2g/kg of IV lipid on day 1 in ELBW and VLBW infants is a recommended clinical practice. This approach will support essential fatty acid needs and minimize energy and protein deficits.

The rate of IV lipid infusion is important, and plasma lipid clearance is improved when IV lipid is given as a continuous infusion over 24 hours (Putet, 2000). Triglyceride concentrations are most often used as an indication of lipid tolerance, and maintaining triglyceride concentrations below 150–200 mg/dL seems reasonable; however, there are no available outcome data supporting this practice. Recommendations for parenteral lipid intake are provided in Table 69.1.

Numerous studies have documented the superiority of 20% over 10% lipid emulsions (Putet, 2000). Lipid clearance is improved with the 20% solutions because they have half the amount of phospholipid emulsifier relative to the same amount of triglycerides. Phospholipids can combine with cholesterol to form lipoprotein X, which ultimately interferes with the clearance of infused triglycerides. Consequently, the use of 10% lipid emulsions should be avoided. A 30% lipid solution has recently become available and may confer even more advantages, although currently there are no comparative data.

IV lipid emulsions may undergo lipid peroxidation, with the formation of organic free radicals, potentially initiating tissue injury. Light, especially phototherapy, may play some role in increasing lipid peroxidation in IV lipid emulsions (Neuzil et al., 1995). However, multivitamin preparations included in the IV solutions are major contributors to generation of peroxides, and lipid emulsions may have only a minor additive effect (Lavoie et al., 1997). Some small studies have suggested that light protection may reduce chronic lung disease, but these results have not been consistent (Chessex et al., 2007; Bassiouny et al., 2009; Sherlock and Chessex, 2009). On the basis of these findings, some clinicians protect IV lipid solutions from light, although the importance or clinical efficacy of this practice remains in doubt. Only a large randomized clinical trial is likely to resolve this issue (Sherlock and Chessex, 2009).

Carnitine facilitates transport of long chain fatty acids through the myocardial membrane and thereby plays an important role in their oxidation. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this finding remains uncertain. Metaanalysis of the studies evaluating carnitine supplementation in parenteral nutrition showed no evidence of effect on ketogenesis, lipid utilization, or weight gain (Cairns and Stalker, 2000). At present, insufficient information is available to support a recommendation for the routine supplementation of carnitine for parenterally fed neonates.

Electrolytes, Minerals, Trace Elements, and Vitamins

Sodium needs are low in the first few days of life because of the expected free water diuresis. For ELBW infants, addition of sodium to the parenteral nutrition solution may not be necessary until about day 3 of life. It is, however, necessary to frequently measure

sodium concentrations and water balance. After the initial diuresis, 2–4 milliequivalent (mEq)/kg per day is usually sufficient to maintain serum sodium in the normal range, but ELBW infants sometimes require higher sodium intakes to compensate for larger renal sodium losses. Chloride requirements follow the same time course as for sodium requirements and are also usually 2–4 mEq/kg per day. Once electrolytes are added to the parenteral nutrition solution, chloride intake should not be less than 1 mEq/kg per day, and all chloride should not be omitted when sodium bicarbonate or acetate is given to correct metabolic acidosis. Potassium requirements are also low in the first few days of life, and potassium should probably be omitted from parenteral solutions in ELBW infants until renal function is clearly established. Potassium intake of 2–3 mEq/kg per day is usually adequate to maintain normal serum potassium concentrations.

Parenteral nutrition solutions usually require the addition of anions, as either acetate or chloride. In general, excess anions should be provided as acetate to prevent hyperchloremic metabolic acidosis. A randomized controlled clinical trial demonstrated that acetate in parenteral nutrition solutions effectively ameliorates this metabolic acidosis (Phelps and Cochran, 1989).

Supplying calcium and phosphorus in parenteral nutrition remains a significant clinical challenge because of limited solubility. It is currently not possible to supply enough calcium and phosphorus to support adequate bone mineralization in preterm infants using the solutions available in the United States. In other countries, organophosphate preparations are available (e.g., glycerophosphate), and calcium and phosphorus can be supplied in parenteral nutrition solutions in amounts that approximate enteral intakes. Precipitation of calcium and phosphorus remains an issue in the United States, however, and the solubility of calcium and phosphorus in parenteral nutrition solutions depends on temperature, type and concentration of amino acid, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium-to-phosphorus ratio, and the presence of lipid. Adding cysteine to parenteral nutrition solutions lowers the pH, which improves calcium and phosphorus solubility. Intakes of 60–80 mg/kg per day of elemental calcium (1.5–2.0 mmol/kg per day) and 48–60 mg/kg per day of phosphorus (1.5–2.0 mmol/kg per day) have been recommended for premature infants receiving parenteral nutrition (Atkinson and Tsang, 2005). A calcium-to-phosphorus ratio of 1.7:1 by weight (1.3:1 by molar ratio) may be optimal for bone mineralization, but it appears that neonates can tolerate and adjust to molar ratios over the range of 0.8 to 1.5 (Atkinson and Tsang, 2005). In general, calcium and phosphorus should be added to parenteral nutrition solutions in early postnatal life. Magnesium is also a necessary nutrient and should be supplied at 3.0–7.2 mg/kg per day. Calcium, phosphorus, and magnesium serum concentrations should be frequently monitored.

Recommendations for trace elements in term and preterm infants are primarily derived from the American Society for Clinical Nutrition guidelines from 1988 (Greene et al., 1988), with some recent updates by the American Society of Parenteral and Enteral Nutrition (Vanek et al., 2012; Finch, 2015). There is reasonable consensus that zinc and selenium should be included early in parenteral nutrition solutions (Finch, 2015). Other trace elements are probably not needed until after the first 2 weeks of life. The recommended intakes of trace elements for term and preterm infants are shown in Table 69.4.

Zinc and copper are available in the sulfate form and can be added separately to parenteral solutions. Several pediatric trace metal solutions are available that contain zinc, copper, magnesium,

TABLE 69.4 Recommended Parenteral Intake of Trace Elements for Term and Preterm Infants

| Trace Element | Term (μg/kg per day) | Preterm (μg/kg per day) |
|------------------------|----------------------|-------------------------|
| Chromium ^a | 0.20 | 0.05–0.30 |
| Copper ^b | 20 | 29 |
| Iron ^c | – | – |
| Fluoride ^d | – | – |
| Iodide | 1 | 1 |
| Manganese ^b | 1 | 1 |
| Molybdenum | 0.25 | 0.25 |
| Selenium ^a | 2 | 1.5–4.5 |
| Zinc ^e | 250 | 400 |

^aRenal dysfunction can cause toxicity.

^bImpaired biliary excretion can cause toxicity.

^cIron not recommended unless on parenteral nutrition for longer than 2 months (estimated daily intravenous requirement is 250–670 μg/kg for term infants and 100–200 μg/kg for preterm infants).

^dBecause of a lack of information on the compatibility of fluoride with TPN and on the contamination level of fluoride in TPN solutions, firm recommendations cannot be made; with long-term TPN (longer than 3 months), a dosage of 500 μg/day may be important in preterm infants, who already have a higher incidence of subsequent dental caries.

^eThe only trace element recommended on day 1 of parenteral nutrition. If the infant requires TPN for longer than 3 months, the dosage must be reduced to 100 μg/kg/day.

Data from Vanek VW, Boren P, Buchman A, et al. A.S.P.E.N. position paper: recommendations for changes in commercially available parenteral multivitamin and multi-trace element products. *Nutr Clin Pract.* 2012;27:440–491.

and chromium in various proportions; these solutions are usually provided at 0.2 mL/kg per day. When trace metal solutions are used, additional zinc is usually needed to provide the recommended intake for preterm infants. In infants with cholestasis, copper and manganese should be discontinued, and chromium and selenium should be used with caution and in smaller amounts in infants with renal dysfunction. At present, parenteral iron is recommended only when preterm infants are nourished exclusively by parenteral solutions for the first 2 months of life.

The recommended intakes of vitamins for term and preterm infants on parenteral nutrition are shown in Table 69.5. Currently only two pediatric multivitamin preparations are available. These preparations provide somewhat higher amounts of most of the B vitamins relative to the recommendations.

Complications of Parenteral Nutrition

Although a wide variety of complications associated with parenteral nutrition were reported in the early days of use, most of these are now rare with current parenteral solutions. Many of the complications (electrolyte and glucose imbalance) can be prevented or corrected by manipulating the constituents of the infusate. The primary complications of parenteral nutrition as currently used are cholestasis and those related to the infusion catheter.

Cholestatic jaundice as a result of hepatic dysfunction is a well-recognized complication of parenteral nutrition. The initial histologic lesion is cholestasis, both intracellular and intracanalicular, followed by portal inflammation and progression to bile duct proliferation after several weeks of parenteral nutrition. Cholestasis most often

TABLE 69.5 Recommended Parenteral Intake of Vitamins for Term and Preterm Infants

| Vitamin | Term (daily dose) | Preterm (dose/kg per day) ^a |
|------------------------------|-------------------|--|
| Fat Soluble | | |
| Vitamin A (IU) | 2300 | 700–1500 |
| Vitamin D (IU) | 400 | 40–160 |
| Vitamin E (IU) | 7 | 2.8–3.5 |
| Vitamin K (μg) | 200 ^b | 10 ^b |
| Water Soluble | | |
| Vitamin B ₆ (μg) | 1000 | 150–200 |
| Vitamin B ₁₂ (μg) | 1 | 0.3 |
| Vitamin C (mg) | 80 | 15–25 |
| Biotin (μg) | 20 | 5–8 |
| Folic acid (μg) | 140 | 56 |
| Niacin (mg) | 17 | 4.0–6.8 |
| Pantothenate (mg) | 5 | 1–2 |
| Riboflavin (μg) | 1400 | 150–200 |
| Thiamin (μg) | 1200 | 200–350 |

^aMaximum not to exceed dosage for term infant.

^bThis does not include the 0.5 to 1 mg of vitamin K to be given at birth.

Data from Vanek VW, Boren P, Buchman A, et al. A.S.P.E.N. position paper: recommendations for changes in commercially available parenteral multivitamin and multi-trace element products. *Nutr Clin Pract.* 2012;27:440–491.

resolves after discontinuation of parenteral nutrition and initiation of enteral feedings. Some rare instances of irreversible liver failure have been documented, but this seems to occur only after several months of use.

The etiology of PNALD cholestasis is unknown and most likely multifactorial. The patients at greatest risk are critically ill premature infants who are susceptible to multiple insults, such as hypoxia, hemodynamic instability, and sepsis. The most frequently identified risk factors in parenteral nutrition–associated cholestasis are duration of parenteral nutrition, degree of immaturity, and delayed enteral feeding (Steinbach et al., 2008). There is also evidence that being small for gestational age is also an independent risk factor for PNALD (Robinson and Ehrenkranz, 2008). A recent systematic review estimated parenteral nutrition–associated cholestasis in premature infants at 25%, but there is substantial variation across studies (Lauriti et al., 2014).

There is growing evidence implicating soybean-derived emulsions in the pathogenesis of PNALD. Soybean-derived lipid solutions contain phytosterols, high concentrations of the proinflammatory omega-6 polyunsaturated fatty acids (PUFAs), and low concentrations of antioxidants (i.e., alpha tocopherol). A variety of both animal and human studies have demonstrated that these components, both alone and in combination, contribute to PNALD (Nandivada et al., 2013).

There are now multiple studies, mostly observational, that demonstrate improvement in PNALD in infants using the fish oil–based product Omegaven (Gura et al., 2008; Diamond et al., 2009; Puder et al., 2009; Park et al., 2015). Puder et al. (2009)

performed an open-label trial of Omegaven in 42 infants with short bowel syndrome with PNALD and compared them with a similar cohort of short bowel syndrome infants who received only soy-based IV lipids. The group receiving Omegaven had lower rates of mortality and liver transplantation and a higher rate of cholestasis reversal. However, this therapy is currently only available in the United States through research or compassionate use protocols. Data from randomized clinical trials are needed before recommending changes in clinical practice to include Omegaven in the treatment of PNALD.

Some infants with cholestasis will require continued parenteral nutrition. In these infants, the use of small-volume enteral feedings in combination with parenteral nutrition may stabilize or improve hepatic function. The use of phenobarbital and ursodeoxycholic acid has been shown to be beneficial in some studies of older children and adults. However, a study in preterm infants demonstrated that tauroursodeoxycholic acid did not prevent the development of parenteral nutrition–associated cholestasis and was ineffective in reducing cholestasis once it occurred (Heubi et al., 2002). At present, the routine use of ursodeoxycholic acid or phenobarbital in parenteral nutrition–associated cholestasis cannot be recommended.

There is emerging information suggesting that lipid restriction may prevent or ameliorate PNALD; however, not all studies have shown this effect (Calkins et al., 2014; Jakobsen et al., 2015). Given the fundamental role of lipid in supporting caloric needs and brain development, lipid restriction should not be routinely used for ELBW and VLBW infants. This strategy might be considered for infants with long-term dependency on parenteral nutrition, but additional studies are needed.

Catheter-related complications remain an important problem associated with parenteral nutrition; the major complication is infection. Two of the most common bacterial pathogens are *Staphylococcus epidermidis* and *Staphylococcus aureus*. Fungal infections also occur, with *Candida albicans* and *Malassezia furfur* being the most common agents. The incidence of sepsis during parenteral nutrition is higher at the lower gestational ages and also increases with the duration of parenteral nutrition. Parenteral nutrition–associated sepsis is likely to be a product of many factors, not the least of which is that the most immature and critically ill patients are most likely to receive parenteral nutrition for prolonged periods. In infants who have developed cholestasis while receiving parenteral nutrition, the rate of sepsis may be increased. At present, avoiding parenteral nutrition–associated infections is best accomplished by meticulous attention to sterile technique in catheter care, early initiation and advancement of enteral nutrition, and prompt removal of the catheter when adequate enteral nutrition is achieved. Prophylactic low-dose vancomycin may diminish the incidence of parenteral nutrition–associated sepsis, but in view of concerns about toxicities and the potential for antibiotic resistance, this approach cannot be recommended (Craft et al., 2004).

Complications specifically related to the catheter have also been reported. Broviac catheters are difficult to place and are associated with thrombosis in neonates (Sadiq et al., 1987). In most NICUs, Broviac catheters have largely been replaced by small-bore Silastic catheters placed percutaneously. However, all central catheters, including the small-bore variety, have produced life-threatening complications. Pericardial tamponade and significant pleural effusions are known complications of the use of central catheters in neonates (Hermansen and Hermansen, 2005). Although these are uncommon events, clinical awareness and early recognition of these complications can prevent mortality.

Use of Parenteral Nutrition in the Neonatal Intensive Care Unit: A Practical Approach

The preceding portion of this chapter has presented the scientific basis for recommendations regarding provision of parenteral nutrition to neonates. The following paragraphs present a practical approach to the administration of parenteral nutrition, with a particular emphasis on ELBW infants.

Every clinician caring for ELBW infants must recognize the urgent need to initiate IV amino acids shortly after birth. As mentioned previously, the ELBW infant loses 1.5% of total body protein each day that amino acids are withheld. Consequently, the goal of early parenteral nutrition should be to limit catabolism and preserve endogenous protein stores. Numerous studies have clearly demonstrated both the safety and efficacy of early amino acids in accomplishing this goal, even at low caloric intakes.

We recommend starting 3.0 g/kg per day of amino acids on the first day after birth. This can be accomplished simply by adding one of the crystalline amino acid solutions designed for use in neonates (Aminosyn-PF, Hospira, Inc.; Primene, Baxter Corporation; Premasol, Baxter Corporation; or TrophAmine, B. Braun Medical, Inc.) to glucose to use as the initial maintenance fluid in ELBW infants. We recommend developing a neonatal amino acid stock solution, made in advance in the pharmacy. The solution contains amino acids in a 7.5% dextrose that, when delivered at 60 mL/kg per day, provides 3 g/kg per day of amino acids. Additional fluids with or without electrolytes and/or a higher concentration of dextrose are “Y’d in,” with adjustments as needed for the individual infant’s fluid, dextrose, and electrolyte requirements, eliminating the need to discard the bag of parenteral nutrition fluid for such changes in status. It is important to note that this stock solution should not be increased beyond 60 mL/kg per day; any alterations to total fluids must be made with ancillary fluids. This mixture of glucose and amino acids can be given via a peripheral IV line, umbilical venous line, or percutaneous central venous catheter. Increased use of percutaneously placed central venous catheters has certainly facilitated early and widespread use of parenteral nutrition in premature infants. In our nursery, strong consideration is given to percutaneous central venous line placement in ELBW infants early in their postnatal course.

To meet growth requirements, 3.5–4.0 g/kg per day of amino acids is required. It is important to point out that such amounts are merely estimates, and protein requirements to sustain optimal growth in ELBW infants might be even higher. Once administration of amino acids is initiated, intake can be advanced to meet requirements for growth over a relatively short period. We typically advance amino acid intake 3.5 g/kg per day by the second day of life. Given the available data, we also recommend the addition of cysteine to the amino acid solution (40 mg/g of amino acids, to a maximum of 120 mg). However, we delay adding cysteine until other electrolytes are included in the parenteral nutrition solution so that acetate can be added to buffer the cysteine acid load.

Glucose should be supplied in a quantity sufficient to maintain normal plasma glucose concentrations. As discussed previously, glucose production and utilization rates are highest in the most premature infants; their glucose needs are in the range of 6–8 mg/kg per minute, whereas the term infant’s needs are approximately 3–4 mg/kg per minute. Giving 10% dextrose at 100 mL/kg per day provides a glucose infusion rate of 7 mg/kg per minute. Starting infants with birthweights less than 1000 g on 5% dextrose is likely to be prudent if their total fluid requirements are greater than 120–150 mL/kg per day.

TABLE 69.6 Caloric Value of Parenteral Nutrition Solutions

| Composition ^a | Kcal/kg per day | % of Nonprotein Calories |
|--|-----------------|--------------------------|
| Example 1: Total Fluids at 110 mL/kg per day | | |
| 10% dextrose | 37 | 55 |
| 3 g/kg per day lipid | 30 | 45 |
| 3.5 g/kg per day amino acids | 14 | — |
| Total | 81 | — |
| Example 2: Total Fluids at 80 mL/kg per day | | |
| 12.5% dextrose | 34 | 53 |
| 3 g/kg per day lipid | 30 | 47 |
| 3.5 g/kg per day amino acids | 14 | — |
| Total | 78 | — |
| Example 3: Total Fluids at 140 mL/kg per day | | |
| 12.5% dextrose | 60 | 67 |
| 3 g/kg per day lipid | 30 | 33 |
| 3.5 g/kg per day amino acids | 14 | — |
| Total | 104 | — |

^aDextrose: 3.4 kcal/g; protein: 4 kcal/g; lipid (20% emulsion): 10 kcal/g.

Lipids should be started within the first 24 hours. We typically start lipids at 2.0 g/kg per day and advance by 0.5–1.0 g/kg per day to a usual maximum of 3 g/kg per day while monitoring and maintaining serum triglycerides at less than 200 mg/dL. Given the numerous advantages over 10% solutions, 20% lipid emulsions should always be used. To facilitate clearance and to avoid impairment of oxygenation, lipids should be infused over a 24-hour period. There is currently no evidence to support the use of cyclic infusion in the acute setting of the NICU.

Caloric goals during parenteral nutrition are lower than with enteral feeds. To achieve optimal protein retention, approximately 70–80 kcal/kg per day is a reasonable goal. To optimize growth, somewhat higher caloric intakes may be necessary. The nonprotein balance between carbohydrate and lipid should be approximately 60:40. These goals can usually be achieved using glucose solutions with concentrations no greater than 12.5% (Table 69.6).

There is a paucity of data related to monitoring laboratory tests during provision of parenteral nutrition. Suggested monitoring for infants receiving parenteral nutrition is shown in Table 69.7. Not all of these laboratory tests may be appropriate in ELBW infants because of constraints related to blood sampling.

The use of parenteral nutrition should be accompanied by the early initiation of enteral feeds (ideally on the first day). Parenteral nutrition should be continued until enteral feedings are well established and providing approximately 100–110 kcal/kg per day, although availability of IV access may necessitate earlier termination of parenteral nutrition in some circumstances. As enteral feeds are advanced, the protein and lipid contents of the parenteral nutrition can be gradually decreased. In addition, careful and prompt attention to reinstitution of parenteral nutrition during episodes of intolerance

TABLE 69.7 Suggested Monitoring During Parenteral Nutrition

| Parameter | Frequency |
|---|--------------------------------------|
| Weight | Daily |
| Length and head circumference | Weekly |
| Serum glucose | 1×/shift during week 1, then daily |
| Serum Na, K, Cl, BUN, Ca, P, Mg, hematocrit | 2–3×/week during week 1, then weekly |
| Alkaline phosphatase, ALT (SGPT), GGT, fractionated bilirubin | Weekly |

ALT, Alanine transaminase; BUN, blood urea nitrogen; GGT, gamma-glutamyl transferase; SGPT, serum glutamate-pyruvate transaminase.

of enteral feeds cannot be overemphasized. Infants with intolerance of enteral feeds in whom nothing-by-mouth (NPO) status is frequently necessary present an additional challenge. In such infants, it may be prudent to determine full-volume parenteral nutrition needs as for NPO status and to then run the parenteral nutrition solution at a lower rate if enteral feeds are administered. With this approach, if a change to NPO status becomes necessary after administration of the parenteral nutrition fluid has begun, the volume can be safely increased without compromising caloric and protein intake.

Acknowledgment

I would like to thank Dr. Brenda Poindexter who contributed to the previous version of this chapter.

Gastrointestinal Tract Development

REED A. DIMMITT, ZACHARY M. SELLERS, AND ERIC SIBLEY

KEY POINTS

- A series of folding, lengthening, and luminal dilation events result in the formation of the foregut (esophagus, stomach, duodenum, liver, and pancreas); the midgut (jejunum, ileum, ascending colon, and transverse colon); and hindgut (descending colon, sigmoid colon, and rectum).
- The molecular mechanisms regulating gastrointestinal (GI) tract tissue development and cellular differentiation involve genetically controlled interactions between trophic compounds and cellular receptors and between nuclear transcription factors and target gene DNA.
- GI microbiota play important roles in gut development.

Structural and Functional Development

Understanding the development of the human gastrointestinal (GI) tract, from both an anatomic and cellular basis, has a long history, dating back more than a century. This knowledge encompasses prenatal in utero and postnatal processes. Changes in both morphogenesis and cellular differentiation drive structural formation of the GI tract in the developing embryo. Digestive function continues to develop following birth. Advances in molecular biology have revealed that specific aspects of GI tract development involve genetically controlled interactions between trophic compounds and cellular receptors, as described later for the different organs of the GI tract.

From a global perspective, the GI tract results from embryonic invagination and folding during week 4 of gestation. Eventually, the buccopharyngeal and cloacal membranes rupture, permitting a direct communication between the fetal GI tract and the in utero environment. A series of folding, lengthening, and luminal dilation events result in the formation of the foregut (esophagus, stomach, duodenum, liver, and pancreas); the midgut (jejunum, ileum, ascending colon, and transverse colon); and hindgut (descending colon, sigmoid colon, and rectum). With additional elongation and growth during the first trimester, the developing gut migrates into the umbilical cord. It returns to the fetal abdominal cavity and rotates counterclockwise around the axis of the superior mesenteric artery at approximately 20 weeks' gestation (Fig. 70.1). Thus by the second trimester, the basic morphogenesis of the fetal GI tract is complete. Additional in utero and postnatal functional maturation is still necessary. For example, GI motility is markedly

disorganized at 24 weeks' gestation. Although dysmotility is a normal developmental "milestone" in the fetal environment, uncoordinated peristalsis in the extremely low birth weight infant is associated with significant postnatal problems.

Knowledge of the cellular and molecular processes of early morphogenesis is rapidly expanding, and these processes involve crosstalk between maternal and fetal factors during development. We first discuss the embryology of the GI tract, in advance of discussing functional development including digestion.

Foregut

Esophagus

The normal morphogenesis of the foregut can be subdivided into five successive developmental stages (Kluth et al., 2003). In the first stage, occurring at days 22 to 23 weeks' gestation, the primitive foregut differentiates into ventral and dorsal structures, termed the *lung field* and *esophageal area*, respectively. The esophageal area has one cell layer consisting of 10 somites. In the second stage, the lung bud develops from the caudal lung field proximal to the liver. Next, in the third stage, longitudinal ridges appear inside the lumen of the developing foregut, which results in a distinct and separate dorsal esophageal area. The fourth stage involves proliferation of the longitudinal ridges, resulting in a tracheo-esophageal septum. Subsequently, apoptosis in the central section of the septum begins the initial separation of the dorsal and ventral compartments. In the fifth stage, there is the formation of definitive respiratory and esophageal structures between weeks 6 and 7 of gestation.

Researchers utilizing *Drosophila* and murine models have identified a myriad of key signaling pathways and transcription factors in foregut development (Jacobs et al., 2012). For example, the hedgehog signaling pathway appears to be essential for maintaining stem cell niches as well as directing developmental axes (Fig. 70.2) (Lees et al., 2005). Hedgehog binds to a cell membrane receptor Patched (Ptc) resulting in downstream signaling and transcription factor-mediated cell differentiation. Defects in this pathway are associated with congenital anomalies of the foregut.

Stomach

By week 6 of gestation, the fetal stomach is well defined. The muscular layers (the inner circular and outer longitudinal) become visible by 9 weeks. By week 12 of gestation, the gastric mucosa

• **Fig. 70.1** Diagrams Showing Normal Rotation Of Alimentary Tract. (A) Fifth week of intrauterine life (*lateral view*). The foregut, midgut, and hindgut are shown with their individual blood supply supported by the common dorsal mesentery in the sagittal plane. The midgut loop has been extruded into the umbilical cord. (B) Eighth week of intrauterine life (*anteroposterior view*). The first stage of rotation is being completed. Note the narrow duodenocolic isthmus from which the midgut loop depends and the right-sided position of the small intestine and left-sided position of the colon. Maintenance of this position within the abdomen after birth is termed *nonrotation*. (C) About the 10th week of intrauterine life, during the second stage of rotation (*anteroposterior view*). The bowel in the temporary umbilical hernia is in the process of reduction; the most proximal part of the prearterial segment entering the abdomen to the right of the superior mesenteric artery is held forward close to the cecum and ascending colon, permitting the bowel to pass under it. As the coils of small intestine collect within the abdomen, the hindgut is displaced to the left and upward. (D) Eleventh week of intrauterine life at the end of the second stage of rotation. From its original sagittal position, the midgut has rotated 270 degrees in a counterclockwise direction about the origin of the superior mesenteric artery. The essentials of the permanent disposition of the viscera have been attained. (A to D from Gardner CE Jr, Hart D. Anomalies of intestinal rotation as a cause of intestinal obstruction. *Arch Surg.* 1934;29:942–946. Copyright 1934, American Medical Association.)

has differentiated into the various types of epithelium: the zymogen, endocrine, mucous, and parietal cells. By 16 weeks, all of these cells are secreting their respective cellular products.

Several trophic factors have been shown to be involved in gastric epithelial differentiation. Crosstalk between transforming growth factor- β 1 and basement membrane protein laminins are important mediators of gastric epithelial polarity (Basque et al., 2002). Fibroblast growth factors 10 and 2, proteins in the hedgehog pathway, are strong determinants of gastric epithelial differentiation, in particular with parietal cell differentiation (Spencer-Dene et al., 2006). Investigators have identified and characterized several other key signaling pathways and transcription factors involved in gastric morphogenesis and cellular differentiation (Kim and Shivdisani, 2016).

Liver and Pancreas

The liver and pancreas develop from two different anatomic domains of the definitive endodermal epithelium of the embryonic foregut. Fate-mapping experiments demonstrate that the liver arises from precursor cells in the developing ventral foregut as well as from a small group of endodermal cells tracking down the ventral midline. During foregut closure, the medial and lateral domains come together. After the initial differentiation, several transcription factors shape the developing liver precursor cells into hepatocytes and bile duct cells (Fig. 70.3) (Zaret and Grompe, 2008; Gordillo et al., 2015). The Wnt/ β -catenin pathway is an integral regulator of liver zonation and proliferation, undergoing tight spatiotemporal regulation. This occurs in part through expression of R-spondin (RSPO) ligands binding to LGR4/5 receptors, leading to increased Wnt

• **Fig. 70.2** Hedgehog Signaling in Mammalian Cells. In the absence of hedgehog Hh (A), the receptor Patched (*Ptc*) exerts an inhibitory effect on Smoothened (*Smo*), a transmembrane protein with homology to G protein-coupled receptors. In the presence of Hh ligand-binding (B), the inhibitory action of *Ptc* on *Smo* is released. The full Gli product is now stabilized and transferred to the nucleus. Once in the nucleus, the full Gli product binds to and upregulates transcriptional targets, including *Ptc* and another Hh-binding protein, *HIP*. In this manner, excess Hh is sequestered and the pathway regulated.

signaling through E3 ubiquitin ligases, zinc and ring fingers (ZNRF3, RNF43). Experimentally, recombinant RSPO1 accelerates liver regeneration following partial hepatectomy, sparking promise for new therapies in liver injury (Planas-Paz et al., 2016).

The pancreas is also induced in lateral endoderm domains, adjacent and caudal to the lateral liver domains, and in cells near the dorsal midline of the foregut. In an even more complex process than the liver, differential expression of transcription factors induces pancreatic progenitor cells to become specific endocrine, acinar, or ductal cells (see Fig. 70.3) (Zaret and Grompe, 2008; Jennings et al., 2015). The first transition in organogenesis is defined by proliferation of pancreatic progenitor cells, followed by differentiation, growth, branching, and cell lineage delineation into endocrine and exocrine subtypes. The final transition involves remodeling, apoptosis, neogenesis, and growth to produce a mature organ (Dassaye et al., 2016).

From an organogenesis aspect, rotation and fusion of the dorsal and ventral pancreatic buds occur by 7 weeks' gestation. By 14 weeks, immunoreactive insulin can be detected, and pancreatic zymogen granules are present in the acinar cells. By 16 weeks, amylase is present. Trypsin, lipase, and amylase are secreted into the duodenum by 31 weeks (Zoppi et al., 1972). As mentioned earlier, the liver is derived as an outbudding from the foregut. The cranial portion of the bud differentiates into hepatic parenchyma and the caudal portion into the gallbladder. Specific hepatic lobules and bile canaliculi can be detected by 6 weeks. Bile acids are

present in the liver by 12 weeks and are actively secreted into the small intestine by 22 weeks' gestation.

Midgut and Hindgut

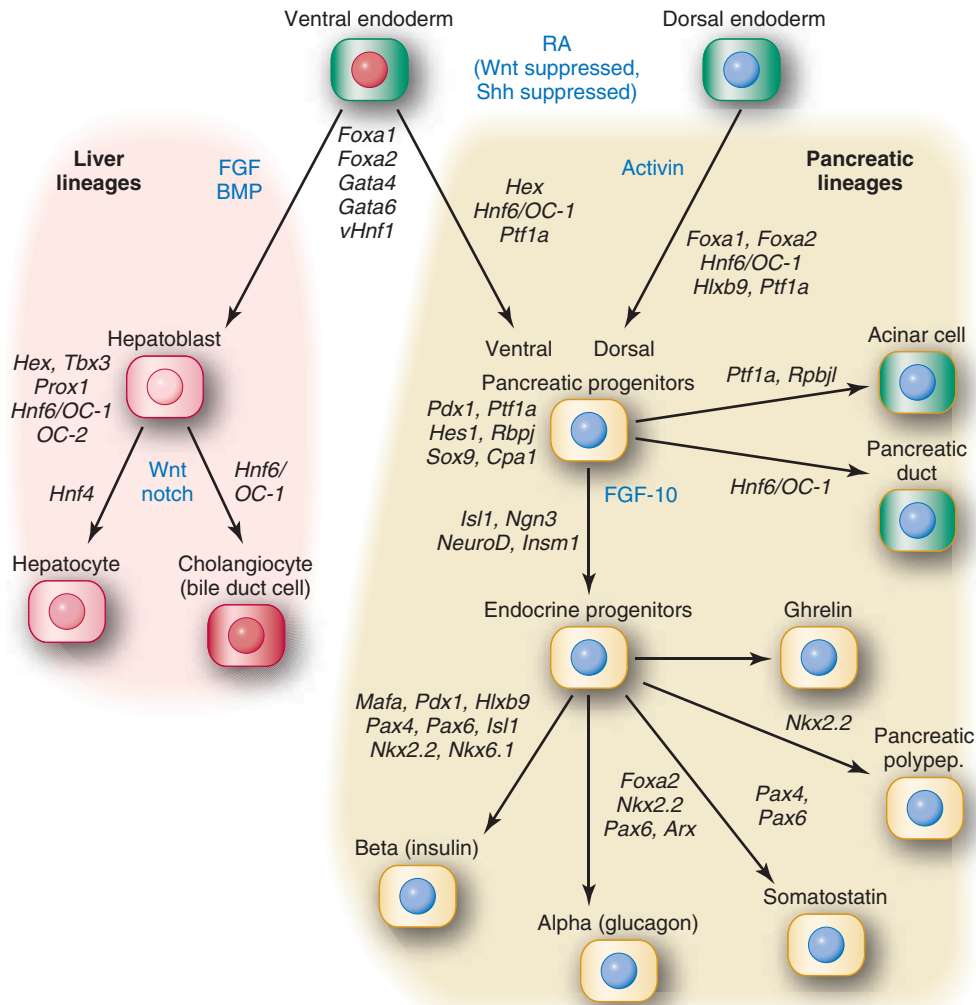

Although portions of the small intestine are derived from the foregut and midgut, and portions of the colon are derived from the midgut and hindgut, we discuss these portions of the GI tract from an end-organ perspective.

Small Intestine

The ultimate digestive function of the small intestine requires intestinal epithelium to secrete digestive enzymes and to provide sufficient surface area to absorb nutrients. Therefore it is important to understand the development of the cellular differentiation as well as overall intestinal length.

As previously mentioned, the hedgehog signaling pathway is also important in endodermal and mesodermal differentiation in small-intestinal development. In addition, the genes *Sox9*, *Sox17*, and *SRY* that encode the corresponding transcription factors have been shown to be essential in endoderm differentiation, whereas the *Hox* family of transcription factor genes are involved in mesodermal differentiation (de Santa Barbara et al., 2003).

After differentiation, the intestinal villous and crypt development is under the control of several growth factors that are secreted in autocrine, paracrine, endocrine, and exocrine pathways (Ménard,

• **Fig. 70.3** Regulatory Factors Controlling Cell Type Lineages Within the Liver and Pancreas. Transcription factor genes involved in differentiation are noted in italics. (From Zaret KS, Grompe M. Generation and regeneration of cells of the liver and pancreas. *Science*. 2008;322:1490–1494.)

2004). Glucagon-like peptide 1 and 2 are secreted by intestinal neurons and L cells, respectively, and are associated with increased intestinal length (Sigalet et al., 2004). Clinical trials in adults are under way administering glucagon-like peptide 2 in patients with short bowel syndrome and may eventually show promise in pediatric patients with intestinal failure. Preclinical experiments show promise that trophic factors, including glucagon-like peptide 2, insulin-like growth factor, and epidermal growth factor, may be beneficial as therapies in neonatal and pediatric short bowel syndrome (Lim et al., 2016). New advances in the generation of intestinal organoids have brought a new dimension to understanding the molecules responsible for intestinal development and in vitro tissue engineering (Clevers et al., 2014).

The small intestine is well developed after its extracorporeal migration into the umbilical cord. Rapid epithelial proliferation occludes the small-intestinal lumen early in development, but the lumen becomes patent at 12 weeks' gestation. There is a gradual development of digestive function that is not fully complete until 34 weeks' gestation, thus posing additional problems regarding the administration of enteral nutrition to premature infants.

Colon

The hindgut is formed by an early dilatation of the fetal cecum at 4 weeks' gestation. By 12 weeks, this primitive structure takes on the gross anatomic features of the colon. At this same time, the midgut rotation is completed, resulting in the cecum being located in the right lower abdominal space. The hallmark of colonic function is coordinated motility, especially in the development of the rectum. The rectum forms by 8 weeks, and formation of complete muscle layers and neural migration of neural crest cells are accomplished by 24 weeks. By 22 weeks, the premature colon maintains some aspects of the small intestine, including villi and disaccharidase function. With developmental maturation, the colonic crypt structures dominate the mucosal surface, and the intestinal characteristics diminish (Raul et al., 1986).

From a cellular developmental aspect, several trophic factors have been linked to colonic differentiation. Elf-3, a member of the Ets transcription factor family, controls intestinal epithelial differentiation during development by regulating the expression of growth factor receptors in epithelial cells (Jedlicka and Gutierrez-Hartmann, 2008). MicroRNAs have been shown to regulate cell

differentiation and maintenance of the pluripotent stem cells (Monzo et al., 2008).

The developing enteric nervous system is derived in a large part from the vagal neural crest cells, with additional contribution from migration of the precursor cells from the sacral region. Molecules that have been shown to control the migration of ganglion cells include the RET/GFRa1/GDNF and endothelin receptor-B/endothelin-3 signaling pathways, transcription factors such as Phox2b, Sox10, Pax3, Mash1, Hox11L1 and Sip1, the hedgehog signaling system, neurotrophins, and bone morphogenetic proteins (Burns and Thapar, 2006; Monzo et al., 2008; McKenna et al., 2010). Defects in these molecules may be related to congenital colonic disease, including Hirschsprung disease.

Mucosal Immune System Development

The GI tract is the largest immune organ in the body and thus warrants review of its development. As with other aspects of GI tract development, the mucosal immune system undergoes both fetal and postnatal changes. The dramatic changes following exposure to food and bacterially derived molecules after birth have been shown to be a major determinant in ongoing mucosal immune modification.

Mucosal immunity is composed of innate and adaptive arms. The innate immune system includes a chemical/noncellular component (e.g., gastric acid, intestinal mucous layer, epithelial barrier function, and defensins), as well as a cellular component (e.g., neutrophils, macrophages, and antigen-presenting cells). The adaptive immune system is made up of T-cell lymphocytes and B-cell-mediated humoral immunity.

Although primarily considered to be involved in digestion, gastric acid, bile salts, and pancreatic secretions function to inhibit potential pathogenic bacterial growth. Clinical investigators have demonstrated that delaying feedings in premature infants results in decreased gastric acid secretion, possibly the mechanism whereby trophic feedings prevent necrotizing enterocolitis (NEC) (Hyman et al., 1983; Berseth et al., 2003). In addition, administering histamine H₂ blockers to premature infants is associated with increased sepsis (Beck-Sague et al., 1994) and NEC (Guillet et al., 2006).

Mucins, glycoproteins, immunoglobulins, glycolipids, trefoil factors, and albumin are all constituents of the luminal mucus layer. Previously, it was believed that mucus functions in a non-specific manner to prevent bacterial adhesion and expel potential pathogens. It is now clear that certain components of the mucus layer are involved in mucosal healing. Specifically, the trefoil factor family has proangiogenic and antiapoptotic qualities, as well as modulating cell-to-cell contacts and potentiating epidermal growth factor (Hoffmann, 2005).

The epithelial barrier function is accomplished by intracellular proteins that anchor the cells to each other, preventing large molecules from penetrating. Recently, it has been shown that these proteins are not just “spot welds” but are dynamic in nature and respond to physiologic and pathologic stimuli (Graham et al., 2009). In addition, dendritic cells, a type of antigen-presenting cell, can sample the microbiota of the intestinal lumen by sending “periscopes” through the tight junctions, suggesting an epithelial-immune cell interaction.

Defensins are antimicrobial proteins secreted by specialized intestinal epithelium called Paneth cells. It appears that defensins are uniformly expressed in the GI tract at 14 weeks’ gestation but are restricted to the small intestine by 17 weeks. The number of

Paneth cells and the expression of defensins in 24-week infants are significantly lower than in term infants and may be associated with increased sepsis and NEC in premature infants (Mallow et al., 1996).

The cellular components of innate immunity include macrophages and granulocytes. Macrophages are present in the fetal intestine as early as week 11 of gestation. A recent study has demonstrated that chemerin is a potent recruiter of intestinal macrophages with peak level production at 20 to 24 weeks (Maheshwari et al., 2009).

Previously, the cells of the innate immune system were believed to act in a nonspecific manner in response to pathogenic stimuli. It is now clear that specific bacterial components signal through membrane-associated receptors termed toll-like receptors (TLRs). For example, lipopolysaccharide from gram-negative bacteria is the ligand for TLR-4, which results in a downstream inflammatory response. TLRs are expressed by both immune cells and GI epithelial cells. TLR4 is expressed on fetal enterocytes as early as 18 weeks’ gestation (Fusunyan et al., 2001) and may be induced following birth with the acquisition of the intestinal microbiota.

The adaptive immune system of host defense is composed of T cells and humoral immunity. Lymphocytes have been shown to proliferate in response to mitogenic stimuli at 12 weeks’ gestation. Peyer patches are lymphoid tissue that process lumen antigens. M cells are differentiated intestinal epithelia that function to process antigens to lymphocytes and other cells in Peyer patches and can be observed at 17 weeks’ gestation. Peyer patches are essential for the production of plasma cells that secrete mucosal associated immunoglobulins.

Once naive T cells interact with antigen, they develop into specific phenotypes based on their cytokine production. Currently, T-cell subsets include T-helper (Th) cell 1, Th2, Th17 (producing IL-17), and regulator T cells (Weaver et al., 2006). In the sterile in utero environment, T cells are predominantly Th2, promoting a symbiosis between fetus and mother. On presentation with antigen, there is a switch to the more mature cells. The gestational age at which this T-cell commitment can occur is unknown and is a fertile area for future research.

Gastrointestinal Microbiota

It is unclear when microbes begin to colonize the human gut, but there is growing evidence that it occurs earlier than previously appreciated. Newborns born vaginally have a different GI microbiota from newborns born by cesarean section, with microbial sequencing on full-term newborns within the first few days of life showing an enrichment of *Bacteroides*, *Bifidobacterium*, *Parabacteroides*, and *Escherichia/Shigella* species in vaginally born newborns. This is in contrast to the *Enterobacter*, *Haemophilus*, *Staphylococcus*, *Streptococcus*, and *Veillonella* species found in cesarean-born newborns (Bäckhed et al., 2015). These differences appear to be related to the initial exposure to the skin and the environment of the surgical field or the vagina, as vaginal flora bacteria can be partially restored by exposing cesarean-born newborns to vaginal secretions (Dominguez-Bello et al., 2016). However, data showing that premature newborns have different microbiota from full-term newborns suggest that the gut may not be sterile before birth. Gram-positive and gram-negative bacteria reside within the basal plate of the placenta, with the placental microbiome having a taxonomic profile similar to the adult oral microbiome (Aagaard et al., 2014).

GI microbiota play important roles in intestinal development, health, and disease. In mice, intestinal microbiota affect villus

height, crypt depth, epithelial cell proliferation, numbers of goblet and Paneth cells, and tight junctions (Yu et al., 2016). Microbiota are involved in the early assembly of intestinal neural circuits and modulate neurotransmitter release via TLR ligands and generation of short-chain fatty acids (Obata et al., 2016). Through luminal antigen sampling, intestinal microbes regulate the immune system. Commensal organisms stimulate the generation of tolerogenic macrophages and dendritic cells, with subsequent generation of regulatory T cells, thereby creating an antiinflammatory environment (Maranduba et al., 2015). The creation of both a local and systemic proinflammatory immune state has been implicated in a growing number of autoimmune diseases, including but not limited to inflammatory bowel disease (Myoshi et al., 2016), type 1 diabetes (Needell et al., 2016), and psoriasis (Zakostelska et al., 2016).

Digestive Physiology

The human GI tract functions to digest and absorb nutrients consumed in food. Nutrient digestion consists of breaking down carbohydrates, proteins, and fats to smaller component molecules (monosaccharides, oligopeptides, and amino acids and free fatty acids and monoglycerides) that can be transported into absorptive intestinal epithelial cells and then into the portal circulation. Human digestive function matures throughout embryogenesis as the GI organs develop and acquire different digestive capacities.

Carbohydrate Digestion

Carbohydrates supply approximately 40% of ingested calories in term newborns. Dietary carbohydrates consist of sugars and starches. Lactose is the predominant sugar in human breast milk and most milk-based infant formulas. Before absorption of its constituent glucose and galactose monosaccharides, the lactose disaccharide must be hydrolyzed by the enzymatic action of the intestinal lactase enzyme. Lactase is a membrane-bound protein present on the apical surface of enterocytes, the intestinal absorptive cells. During early fetal life, the lactase gene is expressed in the colon and small intestine. By term, however, a spatial gradient of lactase gene expression is established, with peak expression in the proximal intestine (Raul et al., 1986). Lactase activity increases during fetal maturation, with the greatest increase, about fourfold, occurring during the third trimester (Weaver et al., 1986). In the absence of sufficient lactase hydrolysis, undigested lactose can result in an osmotic diarrhea. Although preterm infants have relatively low levels of lactase activity, they are often able to sustain normal growth with little diarrhea when fed breast milk or lactose-containing formula (MacLean and Fink, 1980). Some formulas also contain complex carbohydrates in the form of glucose polymers. Glucose polymers require amylase for hydrolysis. The process of complex carbohydrate digestion is initiated in the lumen of the GI tract by the action of alpha-amylases secreted by the salivary gland and the pancreas. Because pancreatic amylase levels are low in neonates, salivary amylase supports a significant amount of glucose polymer digestion along with the mucosal glucoamylase enzyme (Hodge et al., 1983). Glucoamylase is a membrane-bound hydrolase synthesized by the enterocyte that removes single glucose residues from alpha (1–4) chains of glucose polymers. Glucoamylase activity is detectable as early as 13 weeks' gestation and increases twofold to threefold in the near-term newborn (Ménard, 1994).

The monosaccharide products of luminal and membrane-bound hydrolysis of carbohydrates are transported across both the apical and basolateral enterocyte membranes and into the portal circulation. Active glucose and galactose transport into enterocytes are

carried out predominantly by the apical sodium-glucose cotransport protein, SGLT1. Glucose and galactose are transported out of the enterocyte by the basolateral GLUT2 transport protein. Congenital defects of the SGLT1 protein result in rare cases of glucose–galactose malabsorption characterized by severe, watery, acidic diarrhea in the newborn period (Martín et al., 1996). Treatment consists of a glucose-free and galactose-free diet, initially given as a fructose-based formula.

Protein Digestion

Proteins contribute less than 10% of ingested calories in infants. Many of the amino acids used for protein synthesis are produced within the body. Essential amino acids, however, must be provided through dietary protein. Similar to digestion of complex carbohydrates, protein digestion involves both luminal and mucosal enzymatic hydrolysis. Proteins are initially digested within the intestinal lumen by proteases secreted by the stomach (pepsin) and pancreas (trypsin, chymotrypsin, carboxypeptidase, and elastase). The final products of luminal digestion are amino acids and oligopeptides composed of two to six amino acid residues. Digestion of oligopeptides greater than two residues is performed by mucosal membrane-bound brush border peptidases. Bipeptides and tripeptides can be transported through the enterocyte membrane via the proton-coupled PEPT1 transporter and may be further hydrolyzed by cytosolic peptidases that exist within the cell or transported out of the cell and into the portal system as peptides (Liang et al., 1995). Amino acids are transported into enterocytes by a great variety of amino acid transporters. The activities of most of the brush border and cytosolic peptidases are well developed in the preterm infant. There is evidence, however, that some milk proteins may be absorbed intact into the circulation (Kuitunen et al., 1994).

Fat Digestion

Fat provides 40%–50% of the caloric intake of the newborn. Similar to carbohydrate and protein digestion, fat processing is initiated in the lumen before mucosal absorption. By means of enzymatic action, lingual, gastric, and pancreatic lipases function to hydrolyze fat to its constituent free fatty acids and monoglycerides. Pancreatic lipases are in relatively low concentration at birth. Lingual lipases and gastric lipases, however, are present by 26 weeks' gestation and thus contribute significantly to neonatal fat digestion (Hamosh et al., 1981). In addition, a bile-salt-dependent lipase present in human milk is capable of hydrolyzing fats (Freed et al., 1987). Bile salts secreted by the liver and gallbladder are necessary for efficient absorption of fats and function to emulsify fat in the intestinal lumen. Bile flow to the intestine increases rapidly after birth and initiation of feeding. After luminal hydrolysis of fat, mixed micelles of fatty acids and monoglycerides diffuse directly across the cell membrane of mucosal intestinal cells.

Structural Anomalies of the Gastrointestinal Tract

KATHERINE T. FLYNN-O'BRIEN, SAMUEL RICE-TOWNSEND,
AND DANIEL J. LEDBETTER

KEY POINTS

- Small inclusion cysts in the oral cavity are common in newborns and almost always resolve without treatment.
- Suspect the diagnosis of esophageal atresia when there is feeding difficulty with an inability to pass a tube from the nose (or mouth) into the stomach.
- In the most common type of esophageal atresia, there is a fistula from the trachea to distal esophagus (tracheoesophageal fistula [TEF]) that accounts for the air in the gastrointestinal tract (GI) tract seen on radiographs. When no air is seen it suggests that there is only esophageal atresia and no TEF.
- The most important risk factors for mortality in esophageal atresia anomalies are associated prematurity and major congenital heart disease.
- Infants with pyloric stenosis present with nonbilious vomiting of feedings, intravascular volume depletion, and hypochloremic, hypokalemic metabolic alkalosis in the first few weeks of life.
- Bilious vomiting in newborns indicates mechanical obstruction of the GI tract and, specifically, malrotation with midgut volvulus until proven otherwise.
- Suspected midgut volvulus requires urgent surgical evaluation. It is best to make the diagnosis of volvulus when there are signs of intestinal obstruction and not to wait for signs of intestinal ischemia.
- If there is a concern that there may be intestinal malrotation and midgut volvulus, then an urgent upper GI contrast study should be done to evaluate the position of the ligament of Treitz (the transition point between duodenum and jejunum).
- Failure to pass meconium in the first day of life should raise concerns about distal bowel obstruction.
- The way to rule out the diagnosis of Hirschsprung disease in a newborn is by suction rectal biopsy.

This chapter will provide an overview of structural anomalies of the gastrointestinal (GI) tract seen in newborns. Most of the conditions are congenital; however, some are acquired. Although there are an almost limitless number and variety of structural anomalies, we will concentrate on those that are relatively common and those that have important clinical neonatal presentations. The topics will be discussed in anatomic progression, starting from the mouth and ending at the anus.

Several important conditions of the GI tract and abdomen such as biliary atresia, necrotizing enterocolitis (NEC), abdominal wall defects, and abdominal tumors are addressed in other chapters.

Disorders of the Oral Cavity

This section reviews disorders of the epithelial surfaces of the mouth, including cysts and tumors, and disorders of the tongue and salivary glands.

Mouth

Newborns commonly have transient inclusion cysts in the mouth that may be classified into three types: Epstein pearls, Bohn nodules, and dental lamina cysts (Singh et al., 2012; Cizmeci et al., 2014). Epstein pearls are small keratin-filled nodules found in the midline of the palate. They are thought to be epithelial inclusion cysts located at the developmental fusion line of the palate (Singh et al., 2012). Bohn nodules are usually found along the alveolar (dental) ridges and are remnants of developing salivary glands (Singh et al., 2012). Dental lamina cysts are small, raised, white papules in the midline of the palate or on the alveolar (dental) ridges. These are inclusion cysts of the dental lamina, the keratin-producing ectoderm of tooth development. Dental lamina cysts may be isolated or may occur in clusters. They are very common in term newborns with the palatal subtype having a prevalence as high as 65%, and the alveolar subtype having a prevalence of 25%–53%. Although at times concerning in appearance, all three types of oral inclusion cysts are benign and usually asymptomatic. Their natural history is to spontaneously rupture and fuse with the oral epithelium within 5 months of birth, thus conservative management is appropriate and treatment rarely necessary (Singh et al., 2012). Oral inclusion cysts may sometimes be confused with an oral cavity tumor such as a small congenital epulis or with the eruption of a neonatal tooth.

Oral cavity tumors are rare in newborns. The two most common oral cavity tumors are the granular cell tumor and the oropharyngeal teratoma. A granular cell tumor is also known as a *congenital epulis* (“epulis” is a name for any gingival growth). It is a benign tumor that presents as a smooth, red, or pink mass arising from the alveolar (dental) ridge (Kumar et al., 2015).

An oral cavity teratoma arises from the upper jaw or palate and is also known as an *epignathus*. *Teratomas* are tumors that arise from fetal germ cells during development and consist of cells and tissues derived from all three germ cell layers (ectoderm, mesoderm, and endoderm). In the newborn, they are commonly found in the sacrococcygeal region but may occur in the gonads or other midline, or near-midline, locations. Symptoms are typically caused by compression of normal structures, although malignant degeneration may occur.

Larger oral cavity teratomas may be seen on prenatal imaging, but granular cell tumors are typically smaller and discovered on physical examination after birth (Kim et al., 2008). Granular cell tumors and oral cavity teratomas vary in size and, when large, their mass effect may cause feeding difficulty and even upper airway obstruction (Kumar and Sharma, 2008; Kumar et al., 2015). Most oral cavity tumors require surgical resection. The timing of surgery depends upon the severity or potential severity of the symptoms (Kumar and Sharma, 2008; Kumar et al., 2015).

Tongue

The tongue is critical for the important newborn activities of sucking and swallowing, so congenital disorders such as aglossia, ankyloglossia, and macroglossia are usually noted early in life. *Aglossia*, or congenital absence of part or all of the tongue, is a very rare condition caused by failure of tongue embryogenesis in weeks 4 to 8 of gestation. It is usually associated with craniofacial and limb anomalies (Bommarito and Zanato, 2016).

Ankyloglossia is commonly known as *tongue-tie*. By far the most common form of tongue-tie is *ankyloglossia inferior*, which is an abnormally short, thickened, and/or tight inferior frenulum that limits tongue mobility and can interfere with swallowing and speech (Chinnadurai et al., 2015; Francis et al., 2015). Most newborns with ankyloglossia inferior have no difficulty breastfeeding. However, if they do have difficulty with breastfeeding then lactation evaluation and counseling are the next steps, as most will improve without intervention. If feeding difficulties persist then frenotomy, which is the surgical division of the frenulum, may improve feeding. Ankyloglossia inferior may also impact the articulation of speech, but it does not delay overall speech and language development (Chinnadurai et al., 2015). *Ankyloglossia superior* is a rare but more serious anomaly that refers to a fibrous or osseous connection between the tongue and the hard palate. Ankyloglossia superior is associated with other significant anomalies, such as cleft palate, microglossia, micrognathia, GI malformations, and deformed limbs (Bolling et al., 2007; Wieker and Sieg, 2014). Ankyloglossia superior can cause difficulty in feeding and even airway obstruction, making early recognition and treatment necessary (Bolling et al., 2007).

Macroglossia is defined as enlargement of the tongue and may be classified as “true macroglossia” or “pseudomacroglossia” (Perkins, 2009; Klosterman and Tatum, 2015). True macroglossia can be due to muscle hypertrophy of the tongue, which is usually the result of genetic abnormality, such as Beckwith–Weidemann syndrome (Perkins, 2009). Tissue infiltration from amyloidosis, infection, hemangiomas/lymphangiomas, or systemic diseases such as hypothyroidism and diabetes can also lead to macroglossia (Perkins, 2009; Klosterman and Tatum, 2015). *Pseudomacroglossia* occurs when the tongue appears large because of a relatively small oral cavity such as in babies with mandibular hypoplasia (micrognathia) or when the tongue is displaced anteriorly (Klosterman and Tatum, 2015). Surgical treatment is needed if there is airway compromise, dysphagia, or dysarthria. Operations for macroglossia

aim to reduce the size of the tongue and preserve its function (Perkins, 2009; Klosterman and Tatum, 2015).

Salivary Glands

The salivary glands (the parotid, submandibular, and sublingual glands) may be the source of several newborn problems. A *ranula* is a mucus-filled cyst arising from the sublingual gland. In newborns, a ranula is caused by congenital obstruction of a sublingual gland duct (George et al., 2015). Ranulas that are entirely intraoral are known as *simple ranulas*, while those that extend through the floor of the mouth beyond the mylohyoid muscle are known as *plunging ranulas* and present as a submandibular or neck mass (Clyburn et al., 2009). A ranula may be suspected on physical examination, and diagnosis can be confirmed by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). If physical examination and imaging are not definitive then aspiration of the cyst showing yellow fluid containing amylase and mucin confirms the diagnosis (Zhi et al., 2014). Ranulas may spontaneously resolve and thus may be observed for up to 6 months before excision or sclerotherapy (Zhi et al., 2014).

Neonatal suppurative sialadenitis and *parotitis* are rare infections of the salivary and parotid glands, respectively, but should be considered in any newborns presenting with unilateral inflammatory submandibular or parotid swelling (Weibel et al., 2005; Ismail et al., 2013; Ryan and Padmakumar, 2015). Bacterial contamination of the glands is from the oral cavity via the draining ducts or from hematologic spread from transient bacteremia (Spiegel et al., 2004; Miranda and Pereira, 2010; Ismail et al., 2013). Risk factors for these infections include prematurity, prolonged nasogastric feeding, mechanical ventilation, dehydration, and maternal mastitis (Ryan and Padmakumar, 2015). *Staphylococcus aureus* is the most common causative organism, though *Streptococcus* species, *Escherichia coli*, and *Haemophilus influenzae* have also been reported. Treatment with broad-spectrum intravenous antibiotics is recommended, including an antistaphylococcal β -lactam and an aminoglycoside or third-generation cephalosporin (Weibel et al., 2005; Ismail et al., 2013; Ryan and Padmakumar, 2015).

Parotid hemangiomas are the most common salivary gland tumors in newborns. They present as a rapidly growing mass in the preauricular area (Weiss et al., 2011). They may be segmental, involving structures in the distribution of the V3 (mandibular) branch of the trigeminal nerve, including the parotid gland, the overlying skin, and the airway. Alternatively, they may be focal, located within and involving only the parotid gland (Weiss et al., 2011). Hemangiomas traditionally have a rapid growth phase in the first months of life followed by spontaneous involution over the next decade. Diagnosis is by physical examination and is confirmed by imaging with Doppler ultrasound and sometimes MRI (Kollipara et al., 2013). Observation alone is appropriate for small, nondisfiguring lesions with no systemic manifestations such as congestive heart failure. Treatment options include intralesional corticosteroids, systemic nonselective β -blocker (i.e., propranolol), endovascular sclerotherapy, and surgical resection with intraoperative facial nerve mapping (Weiss et al., 2011).

Disorders of the Neck

Although most disorders of the neck are not structural anomalies of the GI tract, abnormalities of the developing oropharynx, including branchial cleft and thyroid anomalies, may present as neck masses. The branchial cleft anomalies usually present as lateral

neck masses and thyroid anomalies usually present as midline neck masses. We will consider these topics and other lateral and midline neonatal neck masses briefly before covering disorders of the esophagus in the next section.

Branchial Anomalies

During early development the flat, trilaminar embryonic disc forms into a cylindrical body, and in the head, neck, and upper chest this process involves the pharyngeal or branchial (Greek for *gills*) apparatus. (*Branchial* is the term most commonly used in clinical medicine to describe these developmental structures so we will use it here.) The branchial apparatus consists of a series of arches that fold and meet in what will be the ventral midline. The arches contain mesoderm and are separated by indentations that on the outer ectodermal surface are called *clefts* and on the inner endodermal surface are called *pouches*. The arches and separating clefts and pouches are numbered based on their cranial to caudal embryonic positioning (Prosser and Myer, 2015) (Fig. 71.1).

Branchial cleft anomalies arise from incomplete obliteration of the embryonic clefts and pouches and result in an epithelial-lined cyst, sinus, or fistula. A cyst has no direct connection from its epithelial inner lining to the normal epithelium of the skin or pharynx. In contrast, a sinus is an abnormal epithelial extension from either the skin or pharynx while a fistula is an abnormal epithelial connection between skin and pharynx. Most branchial cleft anomalies are cysts, and 95% of the cysts arise from the second branchial cleft. Although they are congenital anomalies present since birth, they often present in older children and adolescents or even adults. They usually present as neck masses on the anterior border of the sternocleidomastoid muscle (Prosser and Myer, 2015). These neck masses may be asymptomatic, or they may produce symptoms because of mass effect or infection. Diagnosis of the cyst is made by the characteristic position on physical examination and may be supported by ultrasound, CT, or MRI appearance. A true fistula may be demonstrated by contrast esophagram (Prosser and Myer, 2015; Adams et al., 2016). Treatment of branchial cleft cysts includes initial treatment of any complicating infection and then complete surgical excision when the infection has resolved.

Thyroid

The thyroid may be the source of a neck mass when remnants of its embryologic origin persist and enlarge, when the gland is in an abnormal location, or when it is enlarged in the normal location.

• Fig. 71.1 Branchial Cleft Anomalies.

During weeks 5 to 7 of gestation the rudimentary thyroid migrates from the foramen cecum (i.e., the base of the tongue) to its final position in the lower neck anterior to the trachea (Guerra et al., 2014). At the onset of normal migration the endoderm of the primitive pharynx invaginates and forms the thyroglossal duct with the developing thyroid gland at its inferior aspect. The duct descends to the lower neck and is usually obliterated by week 10 of gestation. Incomplete obliteration of the duct may lead to a thyroglossal duct cyst that presents as a midline neck mass between the hyoid bone and thyroid gland. Thyroglossal duct cysts have a propensity to become infected, and surgical excision is indicated (Simon and Magit, 2012; Eriksi and Hosgor, 2014).

Simple excision of a thyroglossal duct cyst results in a high rate of recurrence, presumably because of small residual bits of thyroglossal duct tissue not in continuity with the main cyst. Therefore the operation of choice is the *Sistrunk procedure*: an en bloc excision of the cyst and its tract, including the middle part of the hyoid bone. Previous infections increase the risk for cyst recurrence after surgery (Simon and Magit, 2012).

Disordered thyroid development may result in abnormally located or ectopic thyroid. In general, functional thyroid tissue not located anterior to the second, third, or fourth tracheal rings is considered to be ectopic. Ectopic thyroid tissue can be found anywhere between the foramen cecum and the mediastinum (Santangelo et al., 2016). The most common location for ectopic thyroid is the tongue. Lingual thyroid results from the failure of normal migration of the thyroid during development and presents as a mass in the posterior midline of the tongue. Most patients with a lingual thyroid do not have additional thyroid tissue in the normal position. A large lingual thyroid may cause symptoms of airway obstruction.

A diffusely enlarged, nontender thyroid gland at birth is known as a *congenital goiter*. It may be associated with hyperthyroidism, hypothyroidism, or a euthyroid state. The diagnosis of congenital goiter can be confirmed with ultrasound. Thyroid function should be assessed to determine the need for thyroid hormone replacement.

Other Neck Masses

Neck masses are often distinguished by their location. As noted, the branchial anomalies usually present as lateral neck masses. The differential for lateral neck masses presenting in the first few weeks of life also includes cystic hygromas and those associated with torticollis.

The “sternocleidomastoid pseudotumor of infancy,” or the neck mass associated with congenital muscular torticollis, is a firm, nontender thickening in the lower half of the sternocleidomastoid muscle. The mass is associated with tightness and shortening of the sternocleidomastoid muscle that leads to a characteristic positioning of the patient’s head—the face turned away from the side of the lesion with the chin tilted up. Range of motion is reduced. The etiology is unknown, but it is associated with difficult deliveries. The condition is more common in males, more frequent on the right, and generally presents in the first few weeks of life (Skelton and Howlett, 2014). Diagnosis is by characteristic examination findings. Treatment is directed at improving the range of motion and posture by physical therapy. Surgery is not usually required.

Cystic hygromas are congenital lymphatic malformations. Lymphatic malformations may be defined by the size of the cystic spaces (<2 cm is microcystic, >2 cm is macrocystic), and location

is based on the de Serres staging system or the Mulliken/McGill system (Adams et al., 2012). Cystic hygromas in the neck are classically macrocystic and located in the posterior triangle, more commonly on the left side. They are present at birth and typically grow with the child but may enlarge suddenly with internal hemorrhage or infection. Treatment is by surgical excision or sclerotherapy. A systematic review in 2012 did not find conclusive evidence to support superiority of one treatment modality over the other (Adams et al., 2012).

In addition to thyroid anomalies, midline neck masses in newborns include dermoid cysts, teratomas, and, rarely, an undescended thymus. Dermoid cysts are subcutaneous cysts lined by keratinized, stratified, squamous epithelium with appendages such as hair follicles, sweat glands, and sebaceous glands (Bloom et al., 2002). They commonly occur on the face and scalp at lines of embryonic fusion and can also occur in the midline neck near the hyoid bone and be confused with thyroglossal duct cysts. They are prone to infection and should be excised. Imaging is not needed for straightforward cases. Teratomas in the neck are often found in the midline and are biologically the same tumor as oropharyngeal teratomas, described in the earlier section. They usually originate near the larynx and trachea and may cause airway obstruction. Almost all midline neck masses require surgical resection.

Disorders of the Esophagus

Newborns with disorders of the esophagus are challenging patients to manage, particularly if they have associated prematurity or congenital heart disease. This section will focus on esophageal atresia and its common variants and then briefly review related congenital conditions such as laryngotracheal cleft, esophageal stenosis, esophageal duplication cyst, and acquired esophageal perforation.

Esophageal Atresia

Esophageal atresia is the most common congenital anomaly of the esophagus and exists when the esophagus is congenitally separated into pieces that are not in continuity. Esophageal atresia is often associated with a tracheoesophageal fistula (TEF).

Epidemiology

The incidence of esophageal atresia is estimated at approximately 1 in 2500 to 1 in 4500 live births with some variation between regions of the world (Kyyronen and Hemminki, 1988; Pedersen et al., 2012). A population-based study from Italy carried out between 1981 and 2012 found 407 cases in 1,417,724 live births for an incidence of 1 in 3500 (Cassina et al., 2016). Esophageal atresia is usually a sporadic disorder, and the recurrence risk for a future sibling is less than 1% (Choinitzki et al., 2013).

Etiology and Associated Anomalies

The basic embryology of the foregut and the variants of esophageal atresia and TEF are not understood completely (Merei and Hutson, 2002; Metzger et al., 2011). Esophageal atresia may be associated with genetic syndromes such as Down syndrome, Edwards syndrome, CHARGE syndrome (coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and development, and ear abnormalities and deafness), Feingold syndrome, and Fanconi anemia (Felix et al., 2007). However, rather than any specific syndrome, esophageal atresia is most often accompanied by additional anomalies in the absence of a known genetic defect

or syndrome. These additional anomalies are commonly in the distribution of VACTERL association (Vertebral defects, Anorectal malformations, Cardiac defects, TracheoEsophageal anomalies, Renal anomalies and Limb abnormalities) (Solomon, 2011). Among 2689 children with esophageal atresia in the United States, 59.1% were found to have associated cardiac defects (most commonly atrial septal defect 46.6% and ventricular septal defect 21.2%). Vertebral, spine, or rib defects were seen in 25.4% of children. Additionally, renal anomalies were associated in 21.8% of children, anorectal malformations in 11.6%, and limb deformities in 6.4%. Approximately one-third of patients had three defects including esophageal atresia, thus qualifying them for a formal VACTERL diagnosis. Duodenal atresia, while not part of VACTERL, was also seen in 4.7% of children with esophageal atresia included in the study (Lautz et al., 2015).

Classification

Esophageal atresias with tracheoesophageal malformations occur as a spectrum of anomalies. Several classification systems have been proposed to name the various arrangements (Vogt, 1929; Gross, 1953); however, in a clinical setting it is best to simply describe the anatomic abnormalities. The most important variants are seen in Fig. 71.2.

Diagnosis

Although the diagnosis of esophageal atresia may be suspected prenatally, the diagnosis is usually made after birth. Prenatal ultrasound showing polyhydramnios and an abnormally small stomach may suggest esophageal atresia; however, both findings are nonspecific (Stringer et al., 1995). If, in addition to polyhydramnios and a small stomach, a dilated esophagus is seen in the neck, a diagnosis of esophageal atresia is more likely (Shulman et al., 2002). Fetal MRI should be considered if prenatal ultrasound suggests esophageal atresia (Langer et al., 2001). Prenatal diagnosis allows opportunity to counsel parents about the diagnosis, postnatal management, and prognosis.

When a neonate is suspected to have esophageal atresia, because of prenatal findings or postnatal clinical symptoms such as excessive drooling, choking, or coughing with feeding, the best way to rule out the diagnosis is to pass a tube into the stomach. A nasogastric (NG) tube that does not pass easily into the stomach, and by X-ray stops or coils in the mid to upper thorax at the 2nd to 4th vertebral body level, is diagnostic of esophageal atresia (Fig. 71.3). A lateral film may demonstrate the tube posterior to the airway, and an air-filled TEF may sometimes be seen. A formal contrast study to outline the pouch is rarely necessary and carries a risk of aspiration.

When esophageal atresia is found, the presence of a distal TEF is confirmed by air in the stomach and intestinal tract (see Fig. 71.3). Absence of air in the abdomen indicates a pure esophageal atresia or an esophageal atresia with an isolated upper pouch TEF (Fig. 71.4). The diagnosis of an isolated TEF without esophageal atresia (i.e., H-type) is often not made at birth because presentation may be subtle. Symptoms can include choking and coughing with feeds and recurrent respiratory infections (caused by aspiration). The abdomen may also appear distended because of excessive air entering the GI tract from the fistula (Karnak et al., 1997). Since the esophagus is intact, a tube will pass normally into the stomach. The diagnosis may be made by bronchoscopy (Fig. 71.5) or specialized imaging studies such as a “pull-back esophagram” (Fig. 71.6) in which contrast is injected as the NG is slowly withdrawn from the stomach to better demonstrate the fistula (Karnak et al., 1997).

• **Fig. 71.4** Radiograph of Pure Esophageal Atresia Without Fistula.

Preoperative Management

When esophageal atresia is diagnosed or suspected, the infant should be promptly evaluated by a pediatric surgeon. In the most common situation, when a TEF to the distal esophagus is present, respiratory distress may result from aspiration of contents of the proximal pouch, aspiration of gastric contents into the trachea, loss of ventilation through the TEF, and compression of the lungs by a distended abdomen. Therefore positive pressure ventilation should be avoided if possible, the patient positioned with the head elevated, and the proximal pouch contents evacuated with an NG tube.

Most commonly, the infant is stable, and there is time before surgery to confirm the diagnosis and to evaluate for associated VACTERL anomalies. The most important investigation is an echocardiogram looking for cardiac defects or great vessel anomalies,

which are present in approximately 18% of cases (Berthet et al., 2015) and can influence the surgical approach. The remainder of the VACTERL work-up including renal ultrasound and spinal imaging may be performed after the operation. Occasionally, inability to ventilate the infant forces an urgent operation to ligate the fistula or decompress the abdomen.

Operation

The primary goal of the initial operation is to divide and close the TEF. Simple ligation (tying off) of the TEF is not recommended because of the high risk of recurrence. Once the TEF is divided an end-to-end esophageal anastomosis should be performed. In unstable or premature infants, it is often safer to perform a staged

• **Fig. 71.5** Bronchoscopy of H-type Tracheoesophageal Fistula.

• **Fig. 71.6** Pull-back Esophagram.

repair by performing the esophageal anastomosis at a later date, after the patient has stabilized and grown (Petrosyan et al., 2009). A long distance between the proximal and distal esophageal segments may also preclude anastomosis at the initial operation. If no anastomosis is performed, a gastrostomy tube should be placed at the initial operation for feeding access until the atresia can be repaired. A chest tube is often placed to evacuate any leakage from the esophageal anastomosis.

Postoperative Management

The infant should be extubated as soon as safely possible to reduce the risk of endotracheal tube and positive pressure trauma to the tracheal suture line. Similarly, deep suctioning should not be done, to avoid injury to the tracheal and esophageal repairs. Likewise, reintubation, if needed, should be performed with *extreme* care. Enteral feedings may be given by gastrostomy or by an NG tube placed across the anastomosis during surgery, or they may be delayed until the anastomosis is judged to be healed and ready for oral feeding or tube placement. We usually perform a contrast study of the esophagus 7 days postoperatively and if the anastomosis has healed, remove the chest tube, although this is not uniform practice (Yanchar et al., 2001).

Outcomes

Overall survival is reported to be 93%, with low birth weight and the presence of major cardiac disease the most important predictors of mortality (Spitz et al., 1994). Ongoing improvements in neonatal critical care have led to greatly improved outcomes in even the smallest premature infants (Lopez et al., 2006; Malakounides et al., 2015).

Early complications after repair of esophageal atresia include anastomotic leak and stricture. Leaks occur in up to 20% of cases although most are small, contained, and heal without another operation (Chittmittrapap et al., 1992). Leaks may be detected by observing saliva in the chest drain but are usually discovered on routine postoperative contrast studies. Stricture at the anastomosis is seen in up to one-third of cases and is more common when the anastomosis was created under tension or was complicated by a postoperative leak (Chittmittrapap et al., 1990). Clinically significant strictures usually manifest with feeding difficulty and can usually be successfully treated with serial dilations (Serhal et al., 2010; Raitio et al., 2016).

Patients who have esophageal atresia commonly suffer from gastroesophageal reflux (GER) and tracheomalacia (Tovar and Fragoso, 2013). GER may be more problematic in patients with esophageal atresia because of inherent dysmotility in the distal esophagus (Kawahara et al., 2007). Routine use of gastric acid blockade is recommended to improve symptoms and to decrease risk of stricture formation because of acid exposure. Many patients go on to require surgical treatment for reflux with fundoplication (Bergmeijer et al., 2000).

Tracheomalacia is a focal or generalized structural weakness of the trachea leading to airway narrowing or collapse with increasing intrathoracic pressure (e.g., expiration). Patients may have expiratory stridor, a “barking cough,” recurrent respiratory illnesses, or acute life-threatening events. Diagnosis is by bronchoscopy, which shows airway collapse during spontaneous breathing. In severe cases, an aortopexy can effectively treat the condition by suspending the aorta (and thus the attached anterior wall of the trachea) to the sternum and thus pulling it away from the posterior wall of the trachea (Corbally et al., 1993; Dave and Currie, 2006).

Laryngotracheoesophageal Cleft

A *laryngotracheoesophageal cleft* (LC) is a rare congenital connection of variable length between the posterior larynx and trachea and the anterior esophagus resulting from failed midline fusion during development. The cleft starts proximally at the larynx and extends distally. The length of the communication can be as short as a

• **Fig. 71.7** Diagram of Laryngotracheoesophageal Cleft.

superficial mucosal defect between the arytenoid cartilages or as long as the entire length of the trachea and even into the mainstem bronchi (Fig. 71.7) (Ryan et al., 1991; Ryan and Doody, 2014). An LC can be associated with Pallister–Hall syndrome, CHARGE syndrome, Opitz G syndrome, or VACTERL association (Leboulanger and Garabedian, 2011). Approximately 12% of infants with LC also have a more distal TEF (Fraga et al., 2015). Symptoms are related to the length of the connection between the esophagus and trachea. Minor defects may cause subtle recurrent aspiration and recurrent respiratory infections. In long defects, there may be an inability to ventilate with severe respiratory distress. It can be difficult to treat the respiratory distress because the endotracheal tube can migrate (“fall”) into the esophagus after placement through the vocal cords. Diagnosis is best made by rigid bronchoscopy, which may also assist in placing the endotracheal tube beyond the distal aspect of the defect. Minor defects are often successfully treated with thickened feeds alone though may be repaired endoscopically (Sandu and Monnier, 2006). Repairs of long defects are major, complex operations of the chest and neck that may require cardiopulmonary bypass.

Congenital Esophageal Stenosis

Congenital esophageal stenosis is rare, with an incidence of 1 in 25,000 to 1 in 50,000 (Vasudevan et al., 2002). It is usually associated with other anomalies, and up to 50% will also have esophageal atresia (McCann et al., 2015). There are three histologic types: (1) fibromuscular thickening, (2) cartilage from ectopic tracheobronchial remnants in the esophageal wall, and (3) membranous web. The majority of defects are found in the distal esophagus, most commonly 1–2 cm above the gastroesophageal junction. More than half of cases are diagnosed after the neonatal period. Dysphagia and recurrent vomiting are common symptoms. Diagnosis can be reliably made with a contrast study and confirmed by endoscopy. Diagnosis is also possible in cases associated with esophageal atresia by evaluation of the distal esophagus during and after surgical repair (Michaud et al., 2013). Treatment is dilation or surgical resection (Vasudevan et al., 2002).

Esophageal Duplication Cyst

Duplications are congenital malformations of unknown etiology that may form anywhere along the length of the developing GI tract but are most common in the small intestine. They may be cystic or tubular. *Esophageal duplication cysts*, also known as *foregut duplication cysts*, are typically covered by a layer of smooth muscle and contain an epithelial lining that can comprise a hybrid histology with elements of respiratory and alimentary tissue within the same lesion (Nobuhara et al., 1997). The lumen of the cyst typically does not communicate with the normal foregut lumen (Michaud et al., 2013).

Clinical presentation is often due to compression of adjacent structures in the chest, and symptoms may include cough, wheezing, and dysphagia. Diagnosis is often made later in childhood (Azzie and Beasley, 2003). The majority of cases have an abnormal chest X-ray because of mass effect, and contrast studies will demonstrate compression on the esophageal lumen. CT often offers better visualization of the lesions (Fig. 71.8) (Shamberger et al., 1995). Treatment is surgical resection (Holcomb et al., 1989).

Esophageal Perforation

Low birth weight neonates are at higher risk for iatrogenic perforation of the esophagus (Hesketh et al., 2015). In a newborn, the presentation of esophageal perforation can mimic esophageal atresia; in both there is inability to pass an orogastric or NG tube into the stomach (Krasna et al., 1987). But when the tube passes beyond the level of the carina but does not enter the stomach it should raise the possibility of perforation because atresias are almost always at or above the carina (see Fig. 71.8). Treatment depends on the location and severity of perforation. When the perforation is small and the leakage of esophageal contents is contained by surrounding structures in the mediastinum, then it may heal with antibiotics alone without surgical repair. Follow-up contrast study to document healing is important before the initiation of feeds. When the perforation and leak of esophageal contents is large, especially with contamination of the pleural space, then urgent surgical intervention is indicated (Mollitt et al., 1981).

• **Fig. 71.9** Radiograph of Pyloric Atresia in the Setting of Epidermolysis Bullosa.

Disorders of the Stomach

The two congenital malformations of the stomach discussed, pyloric atresia and gastric duplication, are quite rare and present with vomiting because of partial or complete obstruction. An acquired gastric obstruction, pyloric stenosis, is much more common and also presents with vomiting later. The last condition reviewed, neonatal gastric perforation, is an acquired condition that presents with peritonitis and even sepsis.

Pyloric Atresia

Pyloric atresia is a congenital, intrinsic, complete obstruction of the pylorus. It is rare, occurring in 1 in 100,000 live births. There are three distinct anatomic variants of pyloric atresia: (1) a simple membrane (57% of cases), (2) replacement by solid tissue (34% of cases), and (3) a complete separation of the stomach and duodenum (9% of cases) (Okoye et al., 2000).

Prenatally, pyloric atresia leads to polyhydramnios and a dilated stomach, thus prenatal diagnosis is common. Nonbilious vomiting occurs with feeds after birth. Diagnosis is confirmed by abdominal radiographs showing air in a dilated stomach but no air in the GI tract distal to the stomach (Fig. 71.9). The lack of a dilated proximal duodenum on imaging studies distinguishes pyloric atresia from the more common duodenal atresia (Fig. 71.10). Babies with pyloric atresia should be evaluated for epidermolysis bullosa (EB) because of the common association of these two rare conditions (Pfendner and Lucky, 2013). The prognosis of patients with EB and pyloric atresia is poor although survivors have been reported (Hayashi et al., 1991). Surgical treatment for all forms of pyloric atresia consists of either removing or bypassing the obstruction.

• **Fig. 71.10** Radiograph of Duodenal Atresia Presenting With a "Double Bubble" Sign.

Gastric Duplication

Gastric duplications are similar to esophageal duplication cysts in that they are surrounded by smooth muscle and usually do not communicate with the lumen of the stomach. They are uncommon and comprise only 5% of abdominal duplications.

They are usually located in the distal stomach, and as they enlarge, they cause symptoms of progressively severe gastric outlet obstruction, with vomiting that is usually nonbilious (Azzie and Beasley, 2003). Approximately one-third of gastric duplications are found in the neonatal period. The diagnosis may be suspected by palpating an upper abdominal mass, by extrinsic compression of the distal stomach on gastrointestinal series (UGI), or by visualizing the mass on ultrasound or CT. Treatment is surgical excision and is recommended even in cases discovered incidentally, since most will eventually cause symptoms of gastric outlet obstruction (Azzie and Beasley, 2003).

Pyloric Stenosis

Pyloric stenosis (or *hypertrophic pyloric stenosis* [HPS]) is an acquired disorder of hypertrophy of the pyloric muscle at the distal end of the stomach. This hypertrophy narrows the gastric outlet and leads to progressively severe, nonbilious vomiting.

Pyloric stenosis is one of the most common structural problems of the GI tract in infants, with an incidence of 2 to 5 in 1000 live births in the Western population. It occurs almost exclusively between weeks 3 to 8 of life. It is four to five times more common in males than in females, and white infants are more commonly affected than black or Asian infants. There is decline in risk with increasing birth order (MacMahon, 2006).

The etiology of HPS is unknown. Genetic factors must have a role since there is an increased risk within families: for example, if a baby has pyloric stenosis then the identical twin has an almost 25% chance of having the condition while a nontwin sibling has a 5.8% chance (MacMahon, 2006). HPS also occurs more frequently than expected in infants with certain syndromes (Panteli, 2009). Exposure to erythromycin and prostaglandins may also increase the risk of developing HPS (Pandya and Heiss, 2012).

As noted, infants with HPS present with a history of vomiting feedings and gastric contents, similar to patients with GER or milk protein allergy. Because the pyloric hypertrophy and degree of gastric outlet obstruction are progressive, the vomiting is also progressively more severe. Unlike intestinal obstructions that are distal to the bile duct insertion in the duodenum, the vomiting in HPS is nonbilious, and the loss of gastric contents undiluted by bile and pancreatic secretions leads to hypochloremic, hypokalemic metabolic alkalosis.

The physical examination of a baby with pyloric stenosis may be notable for dehydration, and in some cases the hypertrophied pylorus may be palpable as a firm, mobile upper abdominal mass known as the pyloric “olive.” The diagnosis is usually confirmed with imaging, most commonly an abdominal ultrasound. Ultrasound findings of pyloric stenosis include a pyloric muscle thickness greater than 3 mm and length greater than 15 mm (Fig. 71.11) (Hernanz-Schulman, 2009). Upper GI contrast radiographs can also confirm the diagnosis of pyloric stenosis if ultrasound is not available.

After diagnosis, the first step in treatment is to correct intravascular volume depletion as this will permit the correction of any associated hypokalemia and alkalosis. The metabolic alkalosis should be corrected before surgery to prevent alkalosis-induced apnea after general anesthesia. It may take a day or more to optimize

• Fig. 71.11 Ultrasound of Hypertrophic Pyloric Stenosis.

intravascular volume, acid–base balance, and serum electrolytes. To limit the risk of aspiration, the stomach should be evacuated with an NG tube from the time of admission and with a larger red rubber catheter immediately before induction of anesthesia.

The operative treatment of pyloric stenosis is to incise and split the pyloric muscle layer completely so that the submucosa is exposed from the duodenum to the gastric antrum. This pyloromyotomy can be achieved by open or laparoscopic approach. The operation is remarkably effective so that feedings can be resumed soon after surgery, and discharge is usually possible within a day or two.

The outcomes of modern management of pyloric stenosis are excellent. Mortality is extremely rare, and there is only a small risk of surgical site infection or wound problems. Other uncommon problems after pyloromyotomy are (1) peritonitis and sepsis from an unrecognized full-thickness mucosal injury and (2) an incomplete myotomy, which can lead to recurrent vomiting (diagnosed by UGI as repeat ultrasound will show postoperative changes). After pyloromyotomy the pylorus eventually heals, remodels, and appears normal. There are no functional abnormalities of the stomach in the long term.

Gastric Perforation

Similar to esophageal perforations, low birth weight infants are thought to be at higher risk for catheter-associated gastric

perforations than term babies. In the absence of obvious trauma, rupture of the stomach is called “spontaneous,” although possible risk factors such as prematurity, duodenal atresia, mechanical ventilation, or neonatal hypoxia are often identified (Leone and Krasna, 2000; Duran et al., 2007). The mechanism of spontaneous gastric perforation is not known, but it appears to be distinct from NEC as NEC typically spares the stomach, and the gross and microscopic appearance seen in NEC and spontaneous intestinal perforation are not seen in spontaneous perforations of the stomach (Holgersen, 1981). Gastric perforations usually present with large amounts of free air on abdominal X-rays. Emergency operation and urgent surgical repair are indicated.

Disorders of the Intestine

Disorders of the intestine reviewed include the potentially life-threatening intestinal malrotation and midgut volvulus, intestinal atresias, enteric duplications, intussusception, and meconium ileus. These conditions present with intestinal obstruction that may be complicated by intestinal ischemia, necrosis, bleeding, perforation, and/or sepsis. The clinical presentations of these conditions and many other GI tract disorders are usually nonspecific and consist of some combination of signs and symptoms such as pain, feeding intolerance, vomiting, lack of stooling, tenderness, distention, or mass.

The history and physical examination often provide clues to the diagnosis. Pain and tenderness may be caused by visceral distention and/or peritoneal irritation. Typically, nonbilious vomiting is seen with obstruction proximal to the ampulla of Vater (the site of bile drainage into the duodenum) while bilious vomiting results from a more distal obstruction. Abdominal distention is usually the result of diffusely dilated loops of bowel caused by either a functional ileus (intestinal stasis with accumulation of swallowed air, feedings, and GI secretions) or a distal obstruction. More-proximal obstructions of the stomach and duodenum usually do not cause abdominal distention. Failure to pass meconium in the first 24 hours of life should raise concern for distal GI obstruction.

A clinical concern for intestinal obstruction requires simultaneous supportive care and diagnostic evaluation. Feedings should be stopped, and if there is abdominal distention or signs of intestinal distention on imaging studies, then gastric decompression via an NG or orogastric tube should be done. Intravenous fluids should be given to meet ongoing maintenance needs, replace any deficits, and account for any ongoing, abnormal losses. Antibiotics should be given when there is concern for infection.

A directed abdominal examination should be done looking for distention, tenderness, localized abdominal edema and erythema, hernias, and masses. Abdominal radiographs can help with diagnosis but are rarely definitive. The characteristic imaging findings of specific disorders will be reviewed. If there are significant concerns for intestinal obstruction then surgical consultation is advised.

Malrotation and Volvulus

Normal intestinal rotation occurs when the midgut that is herniated outside the abdominal cavity into the umbilical cord early in development returns to the abdominal cavity during weeks 10 to 12 of gestation and fixes to the retroperitoneum in a precise pattern. Normal intestinal rotation results in: (1) the duodenum being fixed in the retroperitoneum around the pancreas and transitioning to the intraperitoneal jejunum (visible externally as the ligament

of Treitz) at a point to the left of the spine and above the level of the duodenal bulb, (2) all the small bowel loops floating free in the abdomen, (3) the cecum and ascending colon being attached to the right-lateral posterior body wall up to the hepatic flexure, (4) the descending colon attached to the left-lateral body wall from the splenic flexure to the sigmoid colon, and (5) the blood supply to the entire midgut (jejunum, ileum, and right and transverse colon) attached to the retroperitoneum in a wide pedicle from the ligament of Treitz in the left upper quadrant of the abdomen to the cecum in the right lower quadrant. While a wide spectrum of anatomic abnormalities exists (as a group known as *intestinal rotation anomalies*) (Graziano et al., 2015), we will focus on classic intestinal malrotation where the duodenum does not cross over the spine, and the other normal attachments to the retroperitoneum do not form, resulting in a narrow mesenteric vascular pedicle. This narrow vascular pedicle supports most of the small and large bowel and is prone to twist and cause midgut volvulus. Classic malrotation may be accompanied by abnormal retroperitoneal attachments, known as *Ladd bands*, which cross the second portion of the duodenum.

The true prevalence of malrotation is difficult to determine for several reasons including symptomatic presentation throughout life and a number of children (and even adults) discovered to have asymptomatic variants during imaging studies or operations. Presumably the more severe anatomic abnormalities are more prone to volvulus and present earlier in life, although life-threatening volvulus can occur in adults. The majority of cases, however, present in infancy. Malrotation may occur alone, but it is a regular component of gastroschisis, omphalocele, and congenital diaphragmatic hernia and also may accompany intestinal atresia, intussusception (i.e., Waugh syndrome) (Al Momani, 2014), heterotaxy, and various cardiac defects.

Newborns and infants with midgut volvulus initially present with bilious vomiting, since the twist and obstruction are distal to the ampulla of Vater. Early in the course there may be abdominal pain, but abdominal tenderness and distention may also be absent. As the twist of the mesentery progresses, the blood supply to the bowel is compromised, and intestinal ischemia and eventually intestinal necrosis and peritonitis set in with resulting pain, tenderness, guarding, abdominal distention, and, eventually, signs of sepsis. Abdominal X-rays may be normal or may show a gasless abdomen or distended bowel loops. Laboratory studies may be normal until intestinal ischemia peritonitis and sepsis develop.

Since the entire midgut is potentially at risk for vascular compromise with volvulus, it is best to make the diagnosis at the onset of symptoms and signs of obstruction, before symptoms and signs of intestinal ischemia develop. Since early diagnosis is critical, any newborn or infant with bilious vomiting should be considered to have malrotation and volvulus until proven otherwise, and an urgent upper GI series should be strongly considered. In malrotation, the ligament of Treitz will fail to cross midline to its normal position at the left-sided vertebral body pedicle and will be lower (in the cephalad–caudal axis) than the level of the duodenal bulb (Fig. 71.12).

Other imaging findings suggesting malrotation and volvulus include an abnormal position of the cecum by contrast enema and abnormal relationship of the mesenteric vessels by ultrasound. Malrotation can be also diagnosed by CT, but CT is rarely indicated in newborns. It is important to recognize that volvulus in this setting can be associated with a relatively normal-appearing plain film of the abdomen, and thus a high degree of suspicion must be maintained when clinical findings are suggestive.

• **Fig. 71.12** (A) and (B) Upper Gastrointestinal Series Showing Malrotation With and Without Obstruction/Volvulus.

Midgut volvulus is a surgical emergency. While laparoscopic approaches have been described and may be useful for asymptomatic malrotation, in the setting of acute symptoms an open laparotomy is recommended (Lodwick et al., 2015). The operation of choice is a Ladd procedure that consists of (1) untwisting the volvulized bowel, (2) dividing abnormal bands, (3) broadening of the mesentery, and (4) arranging the bowel so that the midgut mesentery is flat in the retroperitoneum, with the proximal small bowel on the right side of the abdomen and the distal ileum and cecum in the left upper quadrant. The appendix is usually removed since the operation makes its final location unpredictable and diagnosis of appendicitis later in life very difficult. When there is intestinal necrosis, nonviable bowel is excised. When bowel viability is questionable, “2nd look” procedures may be performed. Prophylactic treatment of asymptomatic malrotation may be laparoscopic; however, there is debate as to whether a laparoscopic Ladd procedure is as effective as an open procedure (Graziano et al., 2015; Lodwick et al., 2015). In neonates with congenital heart defects and asymptomatic malrotation, the American Pediatric Surgery Association recommends either observation or postponing the Ladd procedure until after palliation of the congenital heart defect (Graziano et al., 2015).

Intestinal Atresia

Intestinal atresia is a congenital complete obstruction of the bowel lumen. Atresia is an intrinsic problem of the bowel and is not an extrinsic compression. Esophageal and pyloric atresias are discussed in other sections of this chapter. Duodenal atresia and anorectal atresia are considered separately since each has unique embryology, risk factors, and associated conditions. Jejunal, ileal, and colon atresias have many common features and are considered together. Depending upon the anatomic location, some forms of atresia are incomplete and more correctly called intestinal “stenosis,” but the presentation, evaluation, and management are similar, so we will consolidate the discussion of atresias and stenosis together.

Duodenal Atresia

There are several anatomic variations of duodenal atresia including membranous webs, simple occlusions, complete separations of proximal and distal segments, and annular pancreas, in which abnormal fusion of the ventral and dorsal pancreas lead to encirclement of the second portion of duodenum and complete or incomplete obstruction. The exact nature of the developmental abnormality is unknown but may be due to a failure of recanalization (Fairbanks et al., 2006).

The prevalence of duodenal atresia is probably around 1 in 5000 births, but it is not completely clear since many studies evaluate all intestinal atresias rather than duodenal atresia specifically (Sinha et al., 2010). Duodenal atresia is frequently associated with other anomalies including Trisomy 21, VACTERL association, cardiac anomalies, malrotation, anorectal malformations, and biliary tract anomalies, which has important implications for evaluation and management (Escobar et al., 2004; Choudhry et al., 2009).

Duodenal atresia may be suspected prenatally when other associated anomalies or polyhydramnios are present. The diagnosis can be confirmed prenatally by an ultrasound showing a “double bubble” (Choudhry et al., 2009). If the diagnosis is not suspected prenatally, then the typical newborn presentation is vomiting. The vomiting is usually, but not always, bilious since the obstruction is typically distal to the ampulla of Vater. An abdominal X-ray showing a double bubble with no air in the distal GI tract confirms the diagnosis of duodenal atresia (see Fig. 71.10). An X-ray with a double bubble and air present in the distal GI tract indicates the infant may have duodenal stenosis, but malrotation and volvulus must remain a concern.

After the diagnosis, initial management includes gastric decompression with an NG tube, fluid resuscitation, and correction of electrolyte abnormalities. Surgical treatment is bypass of the obstruction, usually with a duodenoduodenostomy. The entire bowel should be evaluated for other intestinal atresias. An open approach is typical; however, a laparoscopic approach has been

described (Kay et al., 2009). Outcomes are generally good, but possible early complications include anastomotic leak and stricture. Potential long-term problems include poor motility of the stomach and duodenum with or without associated megaduodenum (Escobar et al., 2004).

Jejunioleal and Colon Atresia

Jejunioleal and colonic atresias are classified based upon the anatomic abnormality (Fig. 71.13). The etiology of jejunioleal and colon atresia is thought to be due to a prenatal mesenteric vascular compromise. Genetic factors and defective fibroblast growth factor signaling may also play a role in some cases (Fairbanks et al., 2006).

The prevalence of intestinal atresias is 1.6 to 2.8 per 10,000 live births (Cragan et al., 1993; Hemming and Rankin, 2007; Best et al., 2012). Important clinical features of patients with jejunioleal atresia are that about one-third are premature and associated anomalies are less likely, especially compared with patients with duodenal atresia (Adams and Stanton, 2014).

Prenatal ultrasound may show dilated loops of bowel. After birth, neonates with jejunioleal and colon atresia present with bilious vomiting, abdominal distention, and failure or delayed passage of meconium; the more proximal the atresia the more rapid the onset of signs and symptoms. Abdominal radiographs show dilated loops of bowel with airfluid levels and an absence of gas in the rectum. After abdominal X-rays the next step in evaluation of possible intestinal atresia is a contrast enema, which will help differentiate intestinal atresia from uncomplicated meconium ileus, Hirschsprung disease (HD), and small left colon syndrome (Adams

and Stanton, 2014). Contrast enema will also demonstrate that the distal colon is patent, which is important for intraoperative decision making.

Initial management is gastric decompression and fluid resuscitation, followed by operation, which, in addition to repairing the bowel, often involves resection or tapering of large dilated segments that are prone to severe dysmotility.

Early results and long-term outcomes of the operative repair of jejunioleal and colon atresia are good. There is a small risk of surgical site infection and anastomotic leak and stricture. Short bowel syndrome is a potential long-term problem if the atresias lead to loss of a large amount of small-intestinal length.

Newborns with colonic atresia act similarly to those with more proximal atresia; however, because the obstruction is more distal in the GI tract, the presentation is often delayed until the 2nd or 3rd day of life. Abdominal radiographs show dilated distal bowel and may show a very dilated colon if the ileocecal valve prevents air from refluxing back into the distal ileum. Treatment is similar to cases of jejunioleal atresia, with laparotomy, resection of the dilated colon, and anastomosis. Timely diagnosis and treatment are essential and are associated with a generally excellent outcome, while late diagnosis and treatment (over 72 hours from birth) increase the risk of morbidity and mortality (Haxhija et al., 2011).

Meconium Ileus

Meconium ileus is an intraluminal obstruction of the terminal ileum by abnormal meconium. Cystic fibrosis (CF) accounts for 90% of patients presenting with meconium ileus, while up to 20% of patients with CF present as newborns with meconium ileus. CF is caused by mutations in the CF transmembrane regulator (CFTR) that alter bicarbonate and chloride transport. These intraluminal fluid changes may result in the characteristic meconium that adheres to the bowel wall and causes the obstruction. Meconium ileus may be “uncomplicated” and result only in bowel obstruction, or it may be “complicated” when the obstruction leads to prenatal perforation or twisting and ischemia that may cause ileal atresia (Rescorla and Grosfeld, 1993). Note that *meconium peritonitis* is a description of the result of any in utero perforation, whether that perforation is caused by meconium ileus or another problem.

Prenatal diagnosis of CF may be suspected when there is a family history of CF or when the parents are carriers of CFTR mutations. CF diagnosis can be confirmed by fetal DNA analysis and, while neither sensitive nor specific, prenatal ultrasound findings of hyperechoic bowel, bowel dilation, and inability to identify the gallbladder have all been associated with meconium ileus (Carlyle et al., 2012).

The newborn clinical presentation of meconium ileus is similar to a jejunioleal atresia with abdominal distention 12 to 24 hours after birth, vomiting, and failure to pass meconium (Rescorla and Grosfeld, 1993). Abdominal X-rays show dilated loops of bowel suggesting distal intestinal obstruction. If intrauterine perforation has occurred, abdominal distention immediately at birth (rather than several hours later) and abdominal X-rays may show intra-abdominal calcifications.

Initial management of babies with meconium ileus is the same as any neonate with bowel obstruction and includes intravenous fluids, correction of electrolyte abnormalities, and gastric decompression. A contrast enema may confirm the diagnosis and offers the chance of nonoperative management of uncomplicated meconium ileus by instilling water soluble contrast around and into the abnormal meconium, softening it, and encouraging it to pass out

• Fig. 71.13 Types of Intestinal Atresias.

per rectum, thus relieving the obstruction (Carlyle et al., 2012). Hyperosmolar solutions have been advocated to draw fluid into the bowel lumen, but they carry the risk of potentially dangerous intravascular fluid shifts. The administration of *N*-acetylcysteine into the proximal or distal bowel lumen has also been used to help break up the abnormal meconium and relieve the obstruction. Failure of nonoperative measures or the presence of a complicated meconium ileus are indications for surgical intervention.

Operative management of uncomplicated meconium ileus involves laparotomy, opening the small bowel proximal to the obstruction, and irrigation with saline or *N*-acetylcysteine until the obstructing meconium is cleared. The bowel can usually be closed primarily, although sometimes tubes are placed to allow additional irrigation after surgery. By definition, complicated meconium ileus requires an operation. The operation involves resection of compromised bowel, repair of atresias, and, usually, primary anastomosis, although at times temporary diverting stomas are used.

Long-term GI outcomes after nonoperative or operative management of uncomplicated meconium ileus are generally quite good from a surgical perspective, although pancreatic insufficiency requires lifelong medical management.

Enteric Duplication Cysts

Enteric duplication cysts, often simply referred to as *duplications*, can occur anywhere in the alimentary tract from mouth to anus (Gross et al., 1952; Holcomb et al., 1989). Duplications can be cystic or tubular and consist of an inner lining of GI epithelium and an outer layer of smooth muscle. Most duplications occur in the small intestine, especially the distal ileum, and are often on the mesenteric side of the lumen (Fig. 71.14) (Narlawar et al., 2002).

The overall prevalence of duplications is poorly defined, but a cumulative incidence for all sites and all types is probably around 1 in 4000 to 5000, although any specific duplication type or location is quite rare. Various theories exist to explain the embryologic etiology for enteric duplications; however, the split notochord theory is generally accepted (Sharma et al., 2009).

The clinical presentation of an enteric duplication depends on three factors: (1) its location, (2) its relative mass effect, and (3) complications relating to secretions of the involved epithelium

(Azzie and Beasley, 2003). Esophageal and gastric duplication cysts are described in other sections, so this section will focus on small and large bowel duplications. Only about 4%–5% of enteric duplications are located in the duodenum (Macpherson, 1993; Lopez-Fernandez et al., 2013). Duodenal duplications may be connected with biliary or pancreatic ducts. Clinical presentations include asymptomatic masses, GI obstruction, and pancreatitis (Chen et al., 2010; Lopez-Fernandez et al., 2013). Jejunal and ileal duplications often present with bowel obstruction or intussusception. Colonic and rectal duplications are rare but may present with obstruction or volvulus (Holcomb et al., 1989).

Diagnosis is made with ultrasound and/or contrast studies, which may show a filling defect. Ultrasound can be used prenatally, leading to early treatment postnatally (Laje et al., 2010). CT and MRI may be used to define the location and size of the duplication. Treatment is usually surgical excision; however, endoscopic excision has been described for proximal duplications (Meier and Mellinger, 2012).

Intussusception

Intussusception is the telescoping of one portion of bowel into another, usually involving the distal ileum and ascending colon. It usually occurs in older infants and toddlers, but it is also a rare cause of intestinal obstruction in neonates (Aboagye et al., 2014). The presenting symptoms of feeding intolerance, vomiting, abdominal distention, and blood in the stool are nonspecific and can delay diagnosis and treatment (Taskinlar et al., 2014). The diagnosis may be made by ultrasound or contrast enema or may be made at the time of operation for intestinal obstruction. Treatment is surgical reduction with resection if needed.

Disorders of the Colon

Neonatal Appendicitis

Neonatal appendicitis is rare (Karaman et al., 2003). Some cases are associated with HD. The clinical presentation usually includes vomiting, abdominal distention and tenderness, and fever (Raveenthiran, 2015). It is rare to make the diagnosis before an operation is performed for peritonitis because of appendiceal perforation. A possible association with HD has been discussed in the literature, and consideration should be given to a suction rectal biopsy in infants who present with appendicitis.

Hirschsprung Disease

HD is characterized by absence of intrinsic parasympathetic ganglion cells in the submucosal and myenteric plexuses caused by premature arrest of the normal craniocaudal migration of neural crest cells into the bowel wall. HD most commonly involves the rectum and sigmoid colon; however, up to 10% of cases involve the entire colon (i.e., total colon aganglionosis). Rarely, the small intestine is involved (Kessmann, 2006; Amiel et al., 2008). The aganglionic colon has impaired motility and results in a functional distal bowel obstruction of variable severity. It may present as intestinal obstruction in the newborn or constipation in older infants and children. HD may be complicated by enterocolitis, which can cause a clinical picture of marked abdominal distention, pain, tenderness, and systemic manifestations of sepsis. The cause of enterocolitis is unknown; however, it can occur before or after HD is surgically corrected.

• Fig. 71.14 Intraoperative Photo of a Duplication Cyst.

The prevalence of HD is estimated to be 1 per 5000 live births (Amiel et al., 2008). Males are more frequently affected than females (4:1) and Asians, African-Americans, and Caucasians (2.8, 2.1, and 1.5 per 10,000 live births respectively) are more commonly affected than Hispanics (1.0 per 10,000 live births) (Amiel et al., 2008). HD may be an isolated problem; however, almost 20% of cases have chromosomal abnormalities. Although, abnormalities of many genes have been implicated in HD, in the majority of patients the genetic abnormalities have not been defined (Amiel et al., 2008).

When HD presents in a newborn the clinical picture is usually of a distal bowel obstruction with feeding intolerance, vomiting, and abdominal distention. The diagnosis may be suspected when this there is passage of meconium later than 24 hours after birth. Abdominal radiograph may show dilated loops of bowel and paucity of rectal gas. Contrast enema will show normal caliber rectum and distal bowel extending some distance proximally and then a “transition zone” to the dilated, more proximal bowel (Fig. 71.15). Diagnosis is confirmed by rectal biopsies, which show hypertrophic nerve trunks and a lack of ganglion cells (Kessmann, 2006; Amiel et al., 2008).

The surgical treatment of HD involves excision of the abnormally innervated distal colon and a “pull-through” of the normally innervated proximal bowel that is connected to the preserved distal rectum, just above the anal canal, and several different techniques have been described. The procedures may be done in multiple stages, with an initial colostomy and then a definitive pull-through done later, or the procedure may be done in a single stage. In addition, the procedures may be done laparoscopically, open, completely via a transanal approach, or with some combination of approaches.

Potential operative complications include anastomotic leak or stricture or damage to nearby structures, including components of the anal sphincter. The functional outcome for any one patient will not be known for years, when the child reaches the age of

toilet training, but in general, most patients can be expected to achieve social continence and have a good quality of life (Lane et al., 2016). It is important to remember that HD is not cured by surgery (every operation leaves behind an abnormally innervated anal sphincter), but a well-done operation can provide excellent palliation, especially with long-term follow-up and management by appropriate specialists.

Meconium Plug

Meconium plug syndrome is the intraluminal obstruction of the colon by abnormal meconium. This contrasts to the intraluminal obstruction of the terminal ileum in meconium ileus. Infants with meconium plug present with delayed passage of meconium, abdominal distention, and perhaps vomiting (Cuenca et al., 2012). Meconium plug is diagnosed by recognition of the passage of abnormal meconium after rectal stimulation, irrigation, or contrast enema (Fig. 71.16). Contrast enema usually resolves the obstruction, and few infants need surgical intervention, although they may require further evaluation for CF or HD.

Anorectal Disorders

Anorectal malformations (ARMs) are a spectrum of congenital anomalies in which the anus is either absent or abnormally located outside the normal sphincter muscles. ARMs are often described as “high” or “low” depending on whether the rectum ends above or below the levator muscle component of the anal sphincter muscle complex. In this classification of high versus low, those lesions that have fistulae to the urinary tract or vagina are high.

The embryology of ARMs is incompletely understood because they result from a disturbance of the complex coordination of the distal GI tract (the hindgut), distal genitourinary structures

• Fig. 71.15 Contrast Enema of Hirschsprung Disease.

• Fig. 71.16 Contrast Enema of Meconium Plug.

(especially the bladder, urethra, and vagina), and the musculoskeletal components of the pelvis and perineum (Kluth, 2010).

The prevalence of ARMs is about 1 in 5000 live births. Associated anomalies are common. Most notable are those of the VACTERL association. In a large multicenter review, of the 4962 children who underwent ARM repair, 31% had vertebral anomalies, 40% had congenital heart disease, 7% had esophageal atresia (EA)/TEF, 34% had genitourinary anomalies, and 7% had limb defects. Thirty-six percent had three or more defined anomalies and met criteria for the formal VACTERL diagnosis (Lautz et al., 2015). ARMs are also associated with malrotation (Chesley et al., 2015), HD, (Hofmann and Puri, 2013), and Trisomy 21.

Prenatal diagnosis of ARMs is uncommon. After birth the diagnosis of an ARM is dependent upon a good physical examination. Imaging studies are not necessary; however, they can assist in determining the level of defect and the existence of fistula. The normal anus is typically halfway between the coccyx and the scrotum or vaginal orifice, and fistulae associated with ARMs are anterior to the normal position of the anus, with more severe cases entering the urethra, bladder, or vagina (which are not visible on the skin). The absence of an anus is fairly straightforward to determine; however, when there is a fistula on the perineum, especially when the details of its position are obscured by meconium or stool, the diagnosis may be delayed.

The management of patients with ARMs includes supportive care for bowel obstruction, evaluation for possible associated anomalies, and relief of the obstruction. Gastric decompression and intravenous fluids are needed until the bowel obstruction is relieved and enteral feedings are possible. The evaluation for associated anomalies includes a detailed physical examination and imaging studies including echocardiogram, spine radiographs, and renal and spinal ultrasound (Solomon et al., 2014).

Relief of the obstruction usually requires an operation, although some ARMs have a low resistance fistula that allows for spontaneous passage of meconium and stool. ARMs in which the end of the rectum is close to the middle of the anal sphincter complex on the perineum (usually less than 1 cm) can often be corrected with a single, neonatal operation known as an anoplasty. ARMs in which the rectum ends further away from the anal sphincter complex often require a staged approach with an initial colostomy and a later anoplasty and colostomy closure. An anoplasty can usually be performed completely from the perineum, although very high or complex ARMs may require a combined abdominal and perineal approach. The goal of surgical repair of ARMs is to place the rectum into the middle of the anal sphincter complex. The posterior sagittal anorectoplasty, first described by De Vries and Pena in 1982 (De Vries and Pena, 1982), is the most common procedure performed.

The outcomes of ARMs are related to the severity of the anatomic abnormality and to the presence and severity of associated anomalies. Similar to HD, the surgery for ARMs is more palliative than curative, and functional outcomes take years to accurately assess.

A good prognostic sign is the presence of a normal sacrum, presumably because an abnormal sacrum usually means abnormal pelvic innervation. A child with a low ARM and normal sacrum has a good chance of voluntary continence; however, in a child with a high ARM and abnormal sacrum voluntary continence is much less likely. However, many children with relatively severe anatomic anomalies can achieve social continence after a good operation and long-term medical (bowel) management, and many children with less severe anatomic abnormalities also require medical (bowel) management to obtain a good result. Besides incontinence and constipation, other long-term complications may include urinary incontinence, ejaculatory dysfunction, and erectile dysfunction (Rigueros Springford et al., 2016).

Innate and Mucosal Immunity in the Developing Gastrointestinal Tract

STEVEN J. MCELROY, MARK R. FREY, BENJAMIN A. TORRES,
AND AKHIL MAHESHWARI

KEY POINTS

- Development of the human intestinal tract is a complex process that begins in early embryogenesis and continues until the introduction of solid foods in late infancy to early childhood.
- An effective barrier requires the presence of both innate and adaptive immune systems.
- The development, maturation, and maintenance of the intestinal tract's complex functions require interaction with environmental exposures such as amniotic fluid and intestinal commensal bacteria.
- The preterm infant possesses and experiences multiple perturbations to postnatal intestinal and immune development, all of which probably work in concert with one another to increase the vulnerability of the preterm infant to necrotizing enterocolitis.

The fully developed human gastrointestinal (GI) tract reaches a total length of approximately 22 to 30 feet (Hounnou et al., 2002). It has a mucosal surface area of 300 to 400 m² (DeWitt and Kudsk, 1999; Helander and Fandriks, 2014), equivalent to the size of a singles tennis court. Coexistent within the intestinal tract is a diverse microbial community with an abundance of organisms that well exceeds the number of cells in the entire human body (Bjorksten, 2004). During development, the interaction between this microbiome and the intestinal mucosal epithelium is an essential component in the education of the host's immune and inflammatory responses against foreign antigens.

The anatomic and functional development of the GI tract begins during early embryogenesis and continues well into childhood. In addition to the essential digestive and absorptive capacities provided by this organ system, the intestinal tract will also become the largest defense barrier and immune organ in the body. Its complex anatomic structures and dynamic functions protect the host from an onslaught of dietary and environmental antigens, beginning immediately after birth. These multiple layers of intestinal defenses are elegantly coordinated and tightly regulated, as immune and inflammatory responses must constantly balance between aggressive inflammatory attack against potential pathogens and eliciting a tolerant response to environmental antigens that facilitate development. Abnormal development and regulation in the balance between

immune tolerance and inflammatory responsiveness result in an inappropriate host response to antigenic challenges. This increases the vulnerability of the host to diseases of chronic, unregulated inflammation and dysregulated immunity.

Development of the Gastrointestinal Tract

The development of the GI tract spans from early embryogenesis until the introduction of solid foods in late infancy to early childhood. This period of ontogeny can be separated into five developmental phases (Table 72.1, Fig. 72.1) (Wagner et al., 2008). Embryonic organogenesis and primitive gut formation occur in phase I. In phase II, the GI tract becomes a tubular structure, anatomic development (elongation and formation of villus structures) continues, and the functional role of the intestinal epithelium is initiated. Phase III is characterized by rapid linear growth, continued anatomic development of the villus architecture, and ongoing cellular differentiation with maturation of specific cellular physiologic functions. Phase IV begins immediately after birth when postnatal structural and immune development are mediated by the interaction between the host and exogenous, environmental exposures. This developmental phase is mostly directed by the establishment of the intestinal microbiome and the response to dietary factors present in human milk and/or formula. Weaning from human milk or formula and the introduction of solid foods signal the beginning of phase V. During this period, structural development of the intestines and maturation of mucosal immunity are refined (Cummins and Thompson, 2002; Cummins et al., 2006).

Fetal Development

Phases I–III of intestinal development occur in utero. By the end of the first trimester many of the epithelial cellular elements, including specialized cells, have made their appearance (Table 72.2). During this same period, development of the anatomic structures necessary for optimal function of the GI tract proceeds, including formation of crypts and villi. Key microscopic features such as tight junctions (TJs) also occur in this phase. Also in the first trimester and into the second trimester, specialized cells such as goblet, Paneth, enteroendocrine, and the microfold (M) cells appear

TABLE 72.1 Stages of Gut Development

| Stage | Time Period | Development |
|--|-----------------------------------|---|
| Stage I: Embryonic | 0–5 weeks' gestation | Embryonic phase of organogenesis Primitive gut forms Entrance and exit sites of gastrointestinal tract form |
| Stage II: Tubular development | 6–20 weeks | Swallowing begins. Development of villi (8–12 weeks) and crypts (12–19 weeks) Specialized epithelial cells develop; mucin, antimicrobial peptides appear Peyer's patches begin to develop. |
| Stage III: Linear growth and differentiation | 20–40 weeks | Characterized by active differentiation Crypts increase in cell number, causing cells to migrate up villi. Rapid increase in intestinal length (nearly 10 cm/week in the 24–40-week period) Appearance of intestinal enzymes Macrophages, lamina propria lymphocyte populations are established Growth accompanied by selective apoptosis; occurs not only at the tips of villi but also in crypts |
| Stage IV: Mucosal expansion-I | Birth to 5 months, before weaning | Begins after birth with exposure to enteral nutrition Human milk feedings bring about more rapid mucosal differentiation and development than artificial feedings. Mucosal growth continues during infancy: deepening of crypts, increasing villus width and number, and the appearance of submucosal folds. Gastrointestinal tract is confronted with largest antigenic load to body in form of dietary proteins, commensal organisms, and pathogens: greater antigenic load with artificial feedings Mucosal immune system of gut develops extraordinary ability to distinguish between foreign pathogens and safe nutrient proteins and commensal organisms: process facilitated by human milk, leads to effective oral tolerance; success of such local interactions between local innate and specific immunity becomes the prerequisite for lifelong health. |
| Stage V: Mucosal expansion-II | >5–6 months, following weaning | Occurs during weaning phase in late infancy/early childhood during transition from milk feedings to complementary, solid foods Second phase of mucosal expansion associated with epithelial hyperplasia that renders the gut similar in function to that of older children and adults. Larger, lanceolate villi, crypt fissures seen |

Modified from Wagner CL, Taylor SN, Johnson D. Host factors in amniotic fluid and breast milk that contribute to gut maturation. *Clin Rev Allerg Immunol*. 2008;34:191–204.

(Henning, 1985; Buisine et al., 1998; Sanderson et al., 1999; Fusunyan et al., 2001; Rumbo and Schiffrin, 2005; Lin et al., 2008; McElroy and Weitkamp, 2011; Heida et al., 2016).

Role of Amniotic Fluid in Early Gastrointestinal Development

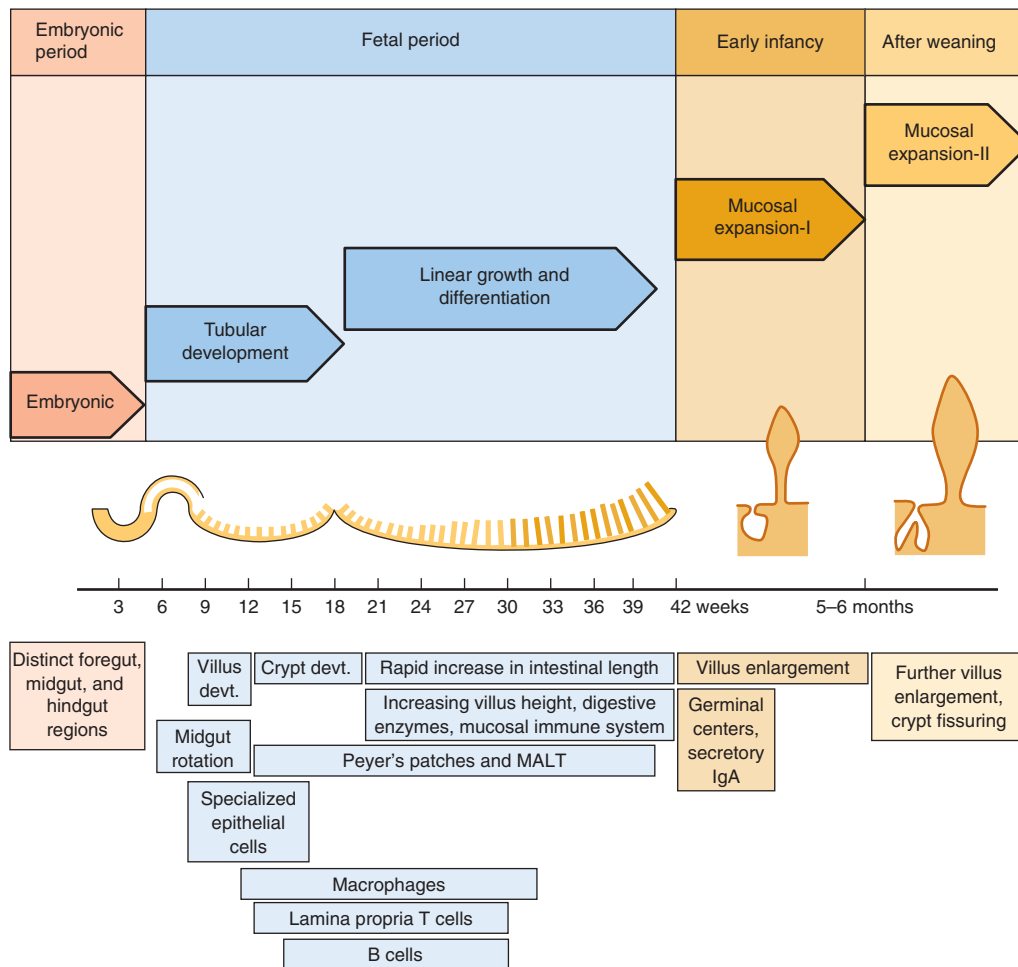

The development, maturation, and maintenance of the intestinal tract's complex functions require interaction with environmental exposures. This process will repeat itself with each changing environment and antigenic exposure. Different periods of new exposure include intrauterine life (fetus), postnatal introduction to the environment and to human milk or formula as the sole dietary source (early infancy), transition to solid foods (late infancy), and expansion of the dietary repertoire and thus the diversity of antigenic exposure (early childhood).

Amniotic fluid is arguably the first “environmental exposure” contributing to GI development. The amniotic fluid cavity is identified early in embryogenesis, and amniotic fluid rapidly accumulates during early gestation (Underwood et al., 2005). Initially, it is predominantly composed of water and solute from maternal plasma that is delivered to the fetus via the placenta and diffuses from the nonkeratinized fetal tissues into the amniotic space. As gestation lengthens, there are other contributors to the contents of amniotic fluid, including the placenta, amniotic

membranes, and the fetus. It is not until the second half of pregnancy that the fetus actively and significantly contributes to the volume and composition of the amniotic fluid, mainly through swallowing and urination (Underwood et al., 2005).

Amniotic fluid is a complex, dynamic mixture. Its composition varies over the gestational period. Proteomic analysis at 16 to 18 weeks' gestation identified more than 500 proteins, although this is likely an underrepresentation (Cho et al., 2007). Amniotic fluid is enriched with hormones, cytokines and growth factors, nutrients and other plasma proteins, modulators of coagulation, modulators of immunity and inflammation, and mediators of cell growth and differentiation, which together facilitate the development of the GI tract and the associated immune system (Box 72.1) (Underwood et al., 2005; Cho et al., 2007; Wagner et al., 2008).

Starting at 8 to 11 weeks' gestation, the fetus ingests increasing amounts of amniotic fluid that may reach 500 mL/day in the third trimester (Pritchard, 1966; Brace et al., 1994; Mann et al., 1996; Montgomery et al., 1999). Thus early in the second trimester until parturition, the intestinal tract of the fetus is continuously bathed in amniotic fluid. In a fetal sheep model (Trahair et al., 1986; Trahair and Harding, 1992), interruption of amniotic fluid ingestion by esophageal ligation during mid-gestation caused mucosal atrophy, villus blunting, and enterocyte abnormalities such as effacement of microvilli, glycogen accumulation, cellular extrusion, and

• **Fig. 72.1** Gastrointestinal Development. The development of the gastrointestinal tract can be separated into five stages, spanning from tubular development in early embryogenesis to late infancy to early childhood. *devt.*, Development; *IgA*, immunoglobulin A; *MALT*, mucosa-associated lymphoid tissue.

lysosomal dysgenesis. Consistent with these findings, human neonates with congenital intestinal obstruction also show villus blunting and shallow, poorly organized crypts distal to the site of obstruction (Condino et al., 2004). In the fetal sheep model described above, the effects of interrupted amniotic fluid swallowing on the intestinal mucosa were gradually reversed following the removal of esophageal ligatures and restitution of amniotic fluid ingestion but not by the infusion of Ringer's lactate. These findings indicated that the "trophic" effects of amniotic fluid were secondary to the bioactive molecules present in amniotic fluid and not merely because of the flow of fluid through the gut lumen (Trahair and Harding, 1995).

A large number of cytokines and growth factors can be detected in amniotic fluid, including epidermal growth factor (EGF), heparin binding-EGF, transforming growth factor (TGF)- β (isoforms TGF- β_1 and TGF- β_2), insulin-like growth factors, hepatocyte growth factor, fibroblast growth factor, chemokines, erythropoietin, and granulocyte colony-stimulating factor (MohanKumar et al., 2017). These cytokines have a complex, multifaceted role in intestinal development. In addition to the cytokines and growth factors delivered to the intestinal mucosa via amniotic fluid, and then after birth, in mother's milk, the fetal/neonatal intestine constitutively expresses many so-called "inflammatory" cytokines and growth factors at levels much higher than in the adult intestine. Intestinal

epithelial cells express cognate receptors for most of these cytokines, and evidence from in vitro and animal models suggests that many of these agents can survive GI digestion and can increase enterocyte proliferation, migration, and differentiation, prevent apoptosis, and promote mucosal restitution (Underwood et al., 2005; Jain et al., 2014; Good et al., 2015; MohanKumar et al., 2017).

Mucosal Immunity in the Developing Gastrointestinal Tract

Soon after delivery, phase IV of GI development begins. The newborn is rapidly presented with environmental, microbial, and dietary stimuli that influence intestinal development and maturation and mucosal immunity. The successful interaction between these antigenic exposures and the host's cellular responses is essential for the development of the innate and adaptive mucosal immunity of the GI tract and ultimately long-term protection of the host. An inappropriate intestinal response to environmental challenges may lead to altered immune and inflammatory regulation with local (GI) and systemic consequences.

However, before understanding the potential influences of environmental exposures on intestinal development and mucosal immunity, the specific structures that exist to coordinate this

interaction must be reviewed. The intestinal components that make up the layers of defense and mediate appropriate oral tolerance or aggressive responsiveness can be found within the epithelial layer, leukocytes in the *lamina propria* and the submucosa, and the structures that comprise the gut-associated lymphoid tissue (GALT).

Physical and Chemical Barriers

On entering the intestinal lumen, a foreign antigen (e.g., bacterial pathogen, food antigen, or xenobiotic) encounters many tightly coordinated layers of mucosal defenses. The first layer of defense is a series of physical and chemical barriers designed to provide constant surveillance and prevent epithelial adherence and translocation of the potential pathogens or passage of antigens between the paracellular spaces. Within this first line of defense are the acidic environment of the stomach, the numerous digestive enzymes that exist along the entire GI route, and bile salts (Martin and Walker, 2008). These factors serve to digest dietary nutrients, but a side

benefit of this digestive process is the destruction of ingested pathogens and other potentially immunogenic proteins into small, nonimmunogenic molecules of less than approximately 10 amino acids in length (Mayer, 2003). Additional mechanisms of the initial mucosal defense include production of mucus by goblet cells to inhibit microbial adherence, presence of polymeric secretory immunoglobulin A (sIgA) within the mucus layer to bind luminal antigens, peristalsis to facilitate removal of antigen-antibody complexes (McElroy and Weitkamp, 2011; Johansson et al., 2013),

secretion of antimicrobial peptides (AMPs) by Paneth cells (Clevers and Bevins, 2013), and maintenance of TJs to prevent paracellular passage (Groschwitz and Hogan, 2009; Marchiando et al., 2011).

Epithelial Cell Layer and Tight Junctions

The intestinal epithelium is a single layer of cells composed of multiple cell types, including enterocytes, enteroendocrine cells, intraepithelial lymphocytes, goblet cells, Paneth cells, tuft cells, and M cells (Fig. 72.2) (Crosnier et al., 2006; Lievin-Le Moal and Servin, 2006; van der Flier and Clevers, 2009). Each of these lineages has individualized specialized functions (discussed in further detail later); together their cell-to-cell interactions and adherence form the basis of the intestinal cell barrier and the first-line defense against the potential penetration of pathogenic bacteria and antigens into the underlying mucosa.

The intestinal barrier is maintained by regulation and maintenance of two pathways: the transcellular pathway and the paracellular pathway (Groschwitz and Hogan, 2009). The paracellular pathway regulates selective transfer of fluids, electrolytes, and small peptides through the intercellular space. It is regulated by three intercellular junctions: TJs, which bind intestinal epithelial cells together near their apical surfaces and regulate the permeability of the monolayer, and the adherens junctions (AJs) and desmosomes, which anchor cells at the lateral surfaces. These junctions are multi-protein complexes that anchor the plasma membrane to the actin cytoskeleton, cluster and organize transmembrane proteins, regulate selective permeability of the epithelium, and promote regulated

extrusion of cells from the intestinal surface (Guan et al., 2011; Marchiando et al., 2011).

TJs may contain up to 40 different transmembrane proteins, including occludin, the claudins, the junctional adhesion molecules, and tricellulin (Ikenouchi et al., 2005; Suzuki, 2013). TJs connect the cell to the intracellular scaffolding through the *zonula occludens* family of proteins (ZO 1–3). In addition, they form pores that contain charged loops of amino acids, which help to regulate the size, strength, and specificity of ions that can pass across the junction (Al-Sadi et al., 2011). The AJs consist primarily of cadherin–catenin complexes (Lievin-Le Moal and Servin, 2006). While TJ proteins control selective porosity of the epithelial barrier, AJs anchor adjacent cells to one another through cytoskeletal interactions (Desai et al., 2013), coordinate cortical actin rings, and serve as a site of intracellular signaling. The AJ also seems to act as a mechanical stress sensor, allowing the plasma membrane to resist tensile forces as cells rearrange during development or homeostasis (Grashoff et al., 2010; Yonemura et al., 2010).

Disruption of junctional proteins is common in inflammatory intestinal diseases (Clark et al., 2006; Bergmann et al., 2013; Hogberg et al., 2013). Tumor necrosis factor (TNF), interferon (IFN)- γ , and nitric oxide can promote the reorganization of junctional proteins and cause barrier dysfunction, such as during necrotizing enterocolitis (NEC) (Elding et al., 2011; Hunter and De Plaen, 2014). In contrast, signaling mediators that enhance or protect TJ formation, such as the short-chain fatty acid butyrate and the amino acid glutamine (Fasano and Shea-Donohue, 2005), tend to be protective against intestinal disorders.

Specialized Epithelial Immune Cells

Goblet cells are a major secretory cellular lineage in the intestinal epithelium that produce mucus, which is composed chiefly of mucins and inorganic salts suspended in water (Lievin-Le Moal and Servin, 2006; Johansson et al., 2013; Kandasamy et al., 2014). The mucus layer adsorbs other glycoproteins, glycolipids, and albumin, and this complex admixture forms a functional, yet highly dynamic barrier between the mucosa and the luminal microbes (Johansson et al., 2013). It also sequesters/stabilizes various bioactive molecules critical for intestinal development, homeostasis, and restitution (Lievin-Le Moal and Servin 2006; Lin et al., 2008; Johansson and Hansson, 2011; Johansson et al., 2013).

More than 20 mucin genes have been identified so far, with *MUC2* being the predominant form produced by intestinal goblet cells (Andrianifahanana et al., 2006; Kandasamy et al., 2014). In the mature intestine, goblet cells increase mucus production upon exposure to inflammatory cytokines such as TNF or bacterial products such as lipopolysaccharides, flagellin A, and lipoteichoic acids (Dharmani et al., 2009). However, in the developing intestine, many of the same inflammatory mediators have a paradoxical, inhibitory effect on mucus production (Levine et al., 1995; McElroy et al., 2011). Consistent with these data, surgically resected tissue samples of human NEC and animal models of NEC-like injury also show a reduction in mucin-positive goblet cells and decreased levels of mucin 2 (Clark et al., 2006; Khailova et al., 2009; Martin et al., 2011; McElroy et al., 2011).

In addition to mucins, intestinal goblet cells also produce intestinal trefoil factor (TFF), specifically TFF3, and resistin-like molecule- β (RELM- β) (Dharmani et al., 2009), which can augment and stabilize the mucus layer (Suemori et al., 1991; Krime et al., 2008). In the adult intestine, goblet cells are capable of presenting low-molecular-weight antigens to dendritic cells (DCs) in the lamina propria (McDole et al., 2012). While the physiologic significance and developmental regulation of this activity are not yet fully understood, it is clear that these cells may have a more complex function in the GI tract than previously appreciated.

Paneth cells are located in the crypt bases and, unlike goblet cells, do not migrate up the crypt-villus axis but remain in the crypt base (Clevers, 2013; Clevers and Bevins, 2013). These cells produce AMPs both constitutively and in response to enteric pathogen exposures (Ouellette, 2010; Salzman, 2010; Bevins and Salzman, 2011). Their position in the crypt base near stem cells allows them to protect these nondifferentiated cells from microbes and thus preserve the regenerative ability of the intestinal epithelium. Paneth cell-derived AMPs are currently categorized into two main families: defensins (α -defensins and β -defensins) and cathelicidins. The antimicrobial activity of these AMPs results from incorporation into the cell membrane and pore formation, causing solute and water influx (Ouellette et al., 1994; Salzman, 2010; Bevins and Salzman, 2011). The α -defensins, also known as cryptdins, are activated by matrix metalloprotease-7 (MMP-7) to acquire microbicidal activity (Schenk and Mueller, 2008). Other bactericidal compounds found in Paneth cells include secretory phospholipase A₂, regenerating islet-derived protein 3 gamma (RegIII- γ), MMP-7, interleukin (IL)-1, TNF- α , IL-1 β , and lysozyme (Salzman et al., 2007; Ouellette, 2010; Bevins and Salzman, 2011; Underwood, 2012; Clevers and Bevins, 2013; McElroy et al., 2013).

Paneth cell disruption can have significant consequences in the intestine, such as impaired clearance of bacterial pathogens (Sherman et al., 2005) or the disruption of normal stem cell function (Clevers, 2013; Clevers and Bevins, 2013) and has been associated with

intestinal disorders such as inflammatory bowel disease and NEC (Wehkamp 2005a, 2005b; McElroy et al., 2011). In addition to the production of AMPs, Paneth cells play important roles in epithelial cell homeostasis (Vaishnava et al., 2011), regulation of splanchnic microvasculature (Stappenbeck et al., 2002), and in the maintenance of the stem cell niche (Sato et al., 2011).

M cells reside within the epithelial cell layer, overlying organized foci of lymphoid tissue. Similar to goblet cells, M cells originate from the crypt, differentiate, and migrate up the crypt-villus axis. However, unlike their neighboring cells, M cells lack microvilli on their luminal surfaces. Rather, the luminal surface has microfolds, giving rise to its name (Mabbott et al., 2013). In addition, the basolateral membrane is invaginated to form a cytoplasmic “pocket” that typically contains lymphocytes and occasionally macrophages or other cells (Schmedtje, 1980; Jarry et al., 1989; Ermak et al., 1994). M cells play an important role in presenting luminal antigens to the cells of the immune system and have been demonstrated in the human fetus as early as 17 weeks (Jakobovits et al., 1972; Bockman and Cooper, 1975; Moxey and Trier, 1978; Braegger et al., 1992; Daya, 1993). The M-cell population expands rapidly in the first postnatal week in animal models, but these changes have not been studied in the human neonate, and their functional role in the human is not well defined (Torres-Medina, 1981; Roy and Ruiz, 1986; Wolf et al., 1987).

Monocytes, Macrophages, Dendritic Cells, and Mast Cells

Macrophages appear in the submucosa and the lamina propria as early as 10 weeks' gestation, and a sizable macrophage population can be seen during mid-gestation (Braegger et al., 1992; Maheshwari et al., 2009, 2011) that develops both from proliferation of resident macrophages and through the recruitment of circulating monocytes (Bain et al., 2014). The expansion of the macrophage population in the intestine contrasts with the lung, where the alveolar macrophage populations remain small in the fetus and expand mainly after birth (Alenghat and Esterly, 1984; Jacobs et al., 1985; Kurland et al., 1988).

In the intestine, resident macrophages are the first cells of the innate immune system to encounter bacteria that breach the epithelium and gain access to the lamina propria (Schenk and Mueller 2008; Farache et al., 2013). In the adult intestine macrophages show a unique functional dichotomy where these cells display avid phagocytic and bactericidal activities but do not show signs of activation or produce cytokines upon exposure to bacterial products (Smythies et al., 2005; Schenk and Mueller, 2008). This “inflammatory anergy” of intestinal macrophages is a result of TGF- β -mediated differentiation and serves to minimize inflammation in the intestinal mucosa despite the close physical proximity to luminal bacteria. In contrast to the adult intestine, the fetal/preterm intestine is developmentally deficient in TGF- β bioactivity (Maheshwari et al., 2011; Namachivayam et al., 2013). Consequently, macrophages newly recruited to the developing intestine tend to retain their inflammatory characteristics and the capacity to produce an exaggerated inflammatory response during bacterial translocation and NEC (Maheshwari et al., 2011).

DCs are antigen-presenting cells (APCs) that are thought to act as an intestinal sentry system by constantly surveying the intestinal lumen. In the adult intestine, DCs use their long projections to sense inflammatory signals and capture luminal antigens and then migrate to secondary lymphoid organs to interact with T-cell lymphocytes (Johansson-Lindbom et al., 2005; Jaensson et al., 2008; Bogunovic et al., 2009; Schulz et al., 2009; Farache et al., 2013). However, there are very limited data on fetal/neonatal

intestinal DCs. Human leukocyte antigen D-related (HLA-DR⁺) DC-like cells can be detected in both lamina propria as well as in the Peyer's patches after 14 weeks' gestation, but these cells may have some overlap with lamina propria macrophages (Spencer et al., 1987; MacDonald, 1996).

Mast cells appear in the intestine mainly after the postnatal microbial colonization. These cells contain large stores of preformed cytokines and chemokines and serve as sentinels that inform about exposure to bacteria or bacterial products in the mucosa (McIlwain et al., 2010). Mast cells also bind IgE via fragment crystallizable region (Fc) epsilon receptors and release histamine and serotonin. These mediators upregulate mucin production, increase intestinal permeability, contract smooth muscle cells, and promote leukocyte recruitment by releasing stored chemokines.

Gut-Associated Lymphoid Tissue and Adaptive Immunity

GALT has two main components: inductor sites and effector sites (see Fig. 72.2) (Magalhaes et al., 2007). The inductor sites represent the structures where immune responses are initiated, namely antigen uptake and processing (Neurath et al., 2002; Magalhaes et al., 2007; Bogunovic et al., 2009). It is within these structures that APCs activate CD4 T cells, CD8 T cells, and B cells. The inductor sites consist of mesenteric lymph nodes, Peyer's patches, isolated lymphoid follicles (ILFs), and cryptopatches, which are clusters of immature lymphocytes that give rise to ILFs.

Rudimentary Peyer's patches become identifiable in fetal ileum at 11 weeks as aggregates of HLA-DR⁺ CD4⁺ lymphoid cells (Spencer et al., 1985; Finke et al., 2002). T and B cells appear at 18 to 20 weeks, and distinct B-cell and T-cell zones can be identified. At 24 weeks, Peyer's patches can be identified macroscopically (Spencer et al., 1985; MacDonald and Spencer, 1994; Husband and Gleeson, 1996). Germinal centers develop after birth (Husband and Gleeson, 1996).

Effector cells are the immune cells, which, once activated, modulate downstream immune and inflammatory signaling. Effector sites are the locations where these effector cells reside; these include the epithelium and the lamina propria. The primary effector cell within the epithelium is the intraepithelial lymphocyte (IEL). IELs are T lymphocytes situated along the basolateral side of the epithelial cell layer. The IEL population is limited in the fetal intestine and develops mainly after birth (Cerf-Bensussan and Guy-Grand, 1991; MacDonald and Spencer, 1994). In contrast, lamina propria lymphocytes reach term levels by 19 to 27 weeks' gestation (Spencer et al., 1986). Functionally, intestinal T cells may take several years to mature; the T-cell receptor β -chain repertoire shows a polyclonal pattern during fetal period and infancy and undergoes gradual restriction to the oligoclonal pattern typical of adults (Williams et al., 2004). Approximately 10%–30% of the IELs may express the $\gamma\delta$ -T-cell receptor (Spencer et al., 1985). These $\gamma\delta$ -T cells may play a role in enterocyte function and antimicrobial immunity and may display cytotoxic activity (Boismenu and Havran, 1994; Komano et al., 1995; Kagnoff, 1998).

In the fetal intestine, B cells are first observed in the lamina propria at 14 weeks' gestation (Spencer et al., 1985). Most of the intestinal B cells show a mature B-cell phenotype (CD20⁺IgM⁺IgD⁺light chain⁺). Although B cells in the fetal intestine include both IgM⁺ and IgG⁺ populations (Rognum et al., 1992), microbial colonization after birth drives the expansion of the IgM⁺ (Fagarasan et al., 2001) and IgA⁺ subsets (Crabbe et al., 1970a, 1970b; Shroff et al., 1995).

Antigen Sampling and Presentation

Bacterial, dietary, and/or xenobiotic antigens that are present in the intestinal lumen are internalized and processed by several pathways involving M cells, intraepithelial DCs, and the enterocytes, which may take up antigens by nonspecific pinocytosis, receptor-mediated endocytosis, or via toll-like receptor (TLR) or nucleotide-binding oligomerization domain (NOD) receptor recognition (Fig. 72.3).

Microfold Cell and Dendritic Cell Pathway

M cells reside within the single-cell epithelial layer and are uniquely positioned over organized sections of lymphoid tissue and Peyer's patches. M cells sample antigens, actively transport them into the submucosa, and present them to effector cells such as DCs and lymphocytes. This process leads to T-cell differentiation and B-cell activation. In the adult intestine, DCs are known to interdigitate their dendritic extensions across the paracellular junctions to sample luminal antigens and then migrate to lymphoid structures to participate in T-cell and B-cell activation. Similar pathways may also be at work in the neonatal intestine.

Receptor-Mediated Endocytosis and Processing: Toll-Like and Nucleotide-Binding Oligomerization Domain Receptors

Pattern recognition receptors (PRRs) such as TLRs, formylated peptide receptors, and NOD receptors recognize and bind to highly conserved specific pathogen regions or molecular motifs, commonly referred to as pathogen-associated molecular patterns (PAMPs) or microbe-associated molecular patterns. The conservation of these molecular motifs among microorganisms of the same class allows the mucosal cell to recognize most microorganisms by using a select group of PRRs. General classes of PAMPs include nucleic acids (e.g., ds ribonucleic acid in viral organisms), polypeptides (e.g., flagellin), and macromolecules (e.g., lipopolysaccharide in the bacterial cell wall of gram-negative organisms and peptidoglycan in the bacterial cell wall of gram-positive organisms) (Louis and Lin, 2009; Tanner et al., 2015).

TLRs are transmembrane proteins that are expressed on the luminal or basolateral surfaces of host defense cells. The extracellular component of leucine-rich repeat recognition domain binds to the specific PAMP, while the intracellular IL-1 receptor-like domain activates cytoplasmic proteins responsible for downstream signaling (Macdonald and Monteleone, 2005; Gribar et al., 2008; Louis and Lin, 2009). The TLR family in mammals consists of TLR1–13 proteins. TLR1–11 are conserved between human and mouse, but TLR10 is not functional in mice (Joosten et al., 2016). Specifically, the human intestine expresses TLR1–9 (Yu and Gao, 2015). Each TLR recognizes and binds with specific PAMPs, some unique to a particular TLR, and some overlapping with other TLRs. TLR4 is preferentially expressed by enterocytes within crypts, whereas TLR2, TLR3, and TLR5 are preferentially expressed on the villus enterocytes (Fusunyan et al., 2001; Winkler et al., 2007; Gribar et al., 2008). NODs are distinct from TLRs in that they reside within the cell's cytoplasm. Of special interest to the intestinal tract, NOD1 and NOD2 (also known as caspase recruitment domain 4 [CARD4] and CARD15) are expressed within intestinal APCs and epithelial cells (Winkler et al., 2007).

The PAMP–PRR complex results in the activation of several well-described cytoplasmic signaling pathways. These pathways include activation of nuclear factor kappa B (NF- κ B), mitogen-activated protein kinase (MAPK), and interferon regulatory factor

• **Fig. 72.3** Antigen Sampling. a_1 , Pinocytosis, receptor-mediated endocytosis; a_2 , apical toll-like receptor (TLR) recognition; a_3 , basolateral TLR recognition; a_4 , nucleotide-binding oligomerization domain receptor recognition; b , microfold cell pathway; c , intraepithelial dendritic cell pathway. Molecular and cellular basis of microflora-host interactions. *J Nutr.* 2007;137:756S–772S.)

(IRF) (Louis and Lin, 2009; Neish, 2009). Modulation of these pathways involves a regulated series of phosphorylation and ubiquitination. With ubiquitination, NF- κ B, MAPK, and IRF are free to translocate into the cell's nucleus and upregulate the production of downstream molecules that combine to initiate an inflammatory response to effectively rid the body of the invading pathogen. This diverse group of molecules includes cytokines, AMPs, chemotactic messengers, adhesion molecules, and other acute-phase reactants. Concomitant with activation of these proinflammatory pathways is the stimulation of apoptotic pathways (via caspases) to assist in the removal of infected or injured cells (Fig. 72.4) (Louis and Lin, 2009; Sharma and Tepas, 2010; Gunther et al., 2013, 2014).

T-Helper 1/T-Helper 2 Polarization

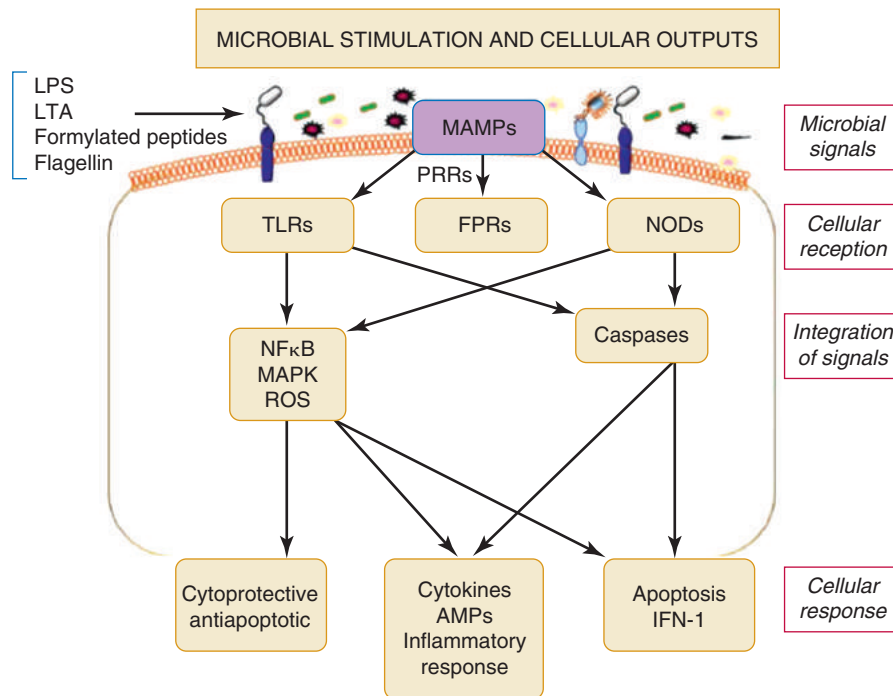

Downstream signaling mediated by PRR–PAMP complexes activates APC differentiation, which in turn modulates the differentiation of T-helper (Th) cells. The specific class of APC mediates the type of differentiation that the Th cells will undergo. For example, the CD8⁺ DC regulates the maturation of the Th cell to a Th1 cell, whereas the CD8-DC activates Th2 cells. Th1 cells increase cytokine production of IFN- γ and lymphotoxin, activate macrophages, and are associated with delayed-type hypersensitivity. Th2 cells increase the production of IL-4, IL-5, IL-9, and IL-13. Th2 cells mediate allergic responses and facilitate antibody production, mast-cell

degranulation, and eosinophil activation (Neurath et al., 2002) (Fig. 72.5).

Exogenous Exposures and Their Impact on Innate Intestinal Immune Defenses

Bacterial Colonization

The average adult human has an intestinal microbiota that consists of 10^{13} to 10^{14} microorganisms representing 800 to 1000 species of bacteria that encode millions of genes (Qin et al., 2010). The abundance of microorganisms increases distally along the intestinal tract (Martin and Walker, 2008). Interestingly, colonization profiles are unique to the location within the intestinal tract, and this is true not just across the major divisions (e.g., ileum vs colon) but also across the microstructures within the gut (e.g., microbiota within the lumen vs within the mucus layer vs within the crypts vs colonization and adherence on the intestinal epithelial cells) (Lievin-Le Moal and Servin, 2006; Romano-Keeler and Weitkamp, 2015). To effectively colonize the intestinal epithelium, bacteria adhere in a lectin-like manner to carbohydrate receptors or glycoconjugates. Glycoconjugate expression is controlled by glycosyltransferase enzymes, which are developmentally regulated, and ongoing maturation of this process is stimulated by colonizing bacteria (Walker, 2002; Forchielli and Walker, 2005).

• **Fig. 72.4** Pattern-Recognition Receptors and Pathogen-Associated Molecular Patterns (Microbial-Associated Molecular Patterns) Complex Activation and Downstream Signaling. Microbial components such as lipopolysaccharide (LPS), lipoteichoic acid (LTA), formylated peptides, and flagellin serve as microbial-associated molecular patterns (MAMPs) and signal pattern-recognition receptors (PRRs) including toll-like receptors (TLRs), formylated peptide receptors (FPRs), or nucleotide-binding oligomerization domain-like receptors (NODs). Integration of these signals evokes cellular outputs based on the initial perception of the triggering organism. Output can be a protective response to commensal microbiota or an inflammatory response to pathogenic organism(s), or it can trigger apoptosis. AMPs, Antimicrobial peptides; IFN-1, interferon-1; MAPK, mitogen-activated protein kinase; NF- κ B, nuclear factor kappa B; ROS, reactive oxygen species. (Reproduced with permission from Sharma R, Young C, Neu J. Molecular modulation of intestinal epithelial barrier: contribution of microbiota. *Jrnl of Biomedicine and Biotechnology*, vol. 2010, Article ID 305879, 15 pages, 2010. doi:10.1155/2010/305879.)

During the first week of life, the bacterial colonization profile of a healthy, full-term newborn is unstable and constitutes a simple array of organisms. This is quickly followed by a persistent, more stable colonization density in the range of 10^9 to 10^{10} per gram of stool (Favier et al., 2002; Palmer et al., 2007; Jost et al., 2012). Once the intestinal flora pattern is established, there is relative stability in this microbial population, with very few shifts in colonization profiles over time. However, shifts do occur, mainly in response to major changes in dietary intake such as introduction of solid foods or with medication use (antibiotics) (Stark and Lee, 1982; Penders et al., 2006; Palmer et al., 2007; Bezirtzoglou et al., 2011; Jost et al., 2012). Within a short period of time after the initiation of a microbial shift, stability is reestablished, and by the end of the first year of life, colonization patterns begin to mirror those seen in adults (Underwood et al., 2015). The timing of microbial colonization and the specific composition of the established microbiome vary with mode of delivery, diet, and other environmental exposures (hospital environment, antibiotic use) (Collado et al., 2015).

Mode of Delivery

At birth, the human newborn has a paucity of bacteria in its intestinal tract. After birth, however, the newborn's intestinal flora rapidly expands (Elgin et al., 2016). Newborns who are born by vaginal delivery have an initial intestinal flora that resembles

maternal vaginal flora, including *Lactobacillus* and *Prevotella* species, whereas newborns born by cesarean delivery have an initial intestinal composition that is more similar to maternal skin flora, including *Staphylococcus* and *Corynebacterium* (Biasucci et al., 2008; Dominguez-Bello et al., 2010). Once colonization does occur, patterns tend to reflect the indigenous microbial population that resides in the infant's environment, with low levels of strict anaerobes such as *Bifidobacterium* and *Bacteroides* and a higher proportion of *Clostridium difficile* (Penders et al., 2006; Adlerberth and Wold, 2009). While it has recently been suggested that the adult microbiome is relatively insensitive to some early-life events, including mode of delivery (Falony et al., 2016), differences in these populations may still play a role in susceptibility to pediatric diseases through altered developmental dynamics.

Diet

Infants fed human milk tend to demonstrate *Bifidobacterium*, a commensal organism with multiple immune benefits, as the predominant organism within their intestinal microbiota (Underwood et al., 2015). Other organisms that may be present in lesser quantities include staphylococci, streptococci, and lactobacilli and other rare anaerobes (Penders et al., 2006; Palmer et al., 2007). In contrast, the intestinal flora of formula-fed infants is more likely to have a greater number of pathogenic species such as Enterobacteriaceae, *Bacteroides* species, and *Clostridium difficile* in their

and to appropriately provide the essential nutrients to optimize the infant's developmental stage. For example, growth and immune factors tend to be higher in preterm milk than in term milk (Walker, 2010; Donovan et al., 2012).

Factors present in breast milk have been shown, in piglet and rodent models, to contribute to the ongoing structural development of the intestinal tract. When provided breast milk (especially colostrum) versus formula or in the absence of any enteral substrate, animals receiving breast milk demonstrate an increase in mucosal

mass and villus height (Sangild, 2006). Morphologic studies of human infants to examine the potential benefits of breast milk are more difficult to perform for obvious reasons. However, studies evaluating diet and intestinal barrier function have been performed in human infants and can be used as an indirect measure for morphologic development and integrity. Indeed, infants fed predominantly formula versus breast milk demonstrated increased intestinal permeability, suggesting compromise in intestinal barrier function (Taylor et al., 2009).

Over time, the composition of formula has been iteratively modified; however, formula continues to fall short of being able to provide the multitude of factors that are present in breast milk, and thus infants fed formula fail to share the same health benefits seen in breastfed infants. Infants fed predominantly breast milk have a reduced incidence of infections (e.g., diarrhea, upper respiratory illness, otitis media, urinary tract infections, bacteremia) (Quigley et al., 2009; Hengstermann et al., 2010), atopic illnesses such as eczema and asthma (Bener et al., 2007), and autoimmune diseases such as diabetes mellitus (Pereira et al., 2014). In preterm infants, those fed breast milk are less likely to develop infections (Hylander et al., 1998) and 10 times less likely to develop NEC compared with infants fed formula (Lucas and Cole, 1990).

Impact of Altered Mucosal Immunity on Early and Later Disease

Developmental immaturity of the immune system, hospital environmental exposures, and medical interventions combine to hamper postnatal development of innate and mucosal immunity in the preterm infant (Table 72.3) (Martin and Walker, 2006). These factors pose potential threats to the preterm infant, particularly to conditions mediated by altered mucosal immunity and intestinal bacterial colonization.

Prematurity and Necrotizing Enterocolitis

Inadequate Physical and Chemical Barriers

The first line of defense of nonspecific physical and chemical barriers is often disrupted because of inadequate production of gastric acidity, digestive enzymes, mucus, Igs, and decreased peristalsis. In addition, common medication exposures (antibiotics, histamine H₂ receptor blockers, vasoconstrictors, sedatives, and paralytics) decrease these inherent defenses by decreasing expression of antibacterial peptides altering natural acidity and decreasing peristalsis (Schumann et al., 2005; Louis and Lin, 2009). As a result, there is a reduced ability to eliminate pathogenic organisms, allowing for increased epithelial adherence and bacterial translocation. Inadequate barrier development is further exacerbated by induced mucosal and villus atrophy that probably develops as a consequence of prolonged absence of enteral feedings (Hartl and Alpers, 2011).

Abnormal Colonization of the Preterm Gut

Although it was once thought that the in utero environment was sterile, bacteria have been identified in early meconium samples in preterm infants, suggesting a potential prenatal influence on early intestinal bacterial colonization (Elgin et al., 2016). Once a broader microbial community has been established, the fecal organisms commonly observed in preterm infants include enterococci, members of Enterobacteriaceae, *Escherichia coli*, staphylococci, streptococci, *Clostridium* species, and *Bacteroides* species (Stark

TABLE 72.3 Neonatal Intensive Care Unit Exposures and Potential Consequences on Intestinal Barrier Defense and Bacterial Colonization in Premature Infants

| | Exposure | Potential Consequences |
|-----------------------------|--|---|
| Nonspecific barrier defense | Prematurity | ↓ immunoglobulin levels ↓ production of digestive enzymes ↓ production of mucus Dysfunctional peristalsis |
| | Delayed feeding | Villous atrophy ↓ production of digestive enzymes ↓ production of mucus ↓ peristalsis |
| | Medications | |
| | Histamine H ₂ receptor blockers | ↓ gastric acidity |
| | Vasopressors and Indocin | ↑ risk for intestinal ischemia and enterocyte injury |
| | Sedatives and paralytic agents | ↓ peristalsis |
| Bacterial colonization | Prematurity | Accentuated inflammatory response Abnormal glycosylation pattern |
| | Delayed feedings | Delay in bacterial colonization |
| | Broad-spectrum antibiotics | Prolonged sterilization of gut Delayed colonization of beneficial, commensal bacteria Preferred bacterial colonization of pathogenic bacteria |
| | Formula feeding and hospitalization | Preferred bacterial colonization of pathogenic bacteria |

From Martin CR, Walker WA. Intestinal immune defences and the inflammatory response in necrotising enterocolitis. *Semin Fetal Neonatal Med.* 2006;11:369–377.

and Lee, 1982; Palmer et al., 2007; Jost et al., 2012; La Rosa et al., 2014; Elgin et al., 2016). This bacterial profile is distinctly different from those seen in breastfed term infants, yet similar to patterns exhibited by formula-fed full-term infants (Schwartz et al., 2003; Arboleya et al., 2012a). However, in contrast to formula-fed term infants, the colonization by these pathogenic bacteria persists longer (Arboleya et al., 2012a, 2012b, 2015), and there is slow development of increased species diversity with a nonrandom progression toward a *Clostridium*-dominated biome (Schwartz et al., 2003; La Rosa et al., 2014).

The differences in bacterial colonization patterns between healthy, full-term infants and preterm infants can be partially explained by the inadequate physical and chemical barriers described above, which allow for greater penetration and adherence by pathogenic organisms. Additional key factors include immaturity of epithelial glycoconjugate expression (an important modulator of bacterial

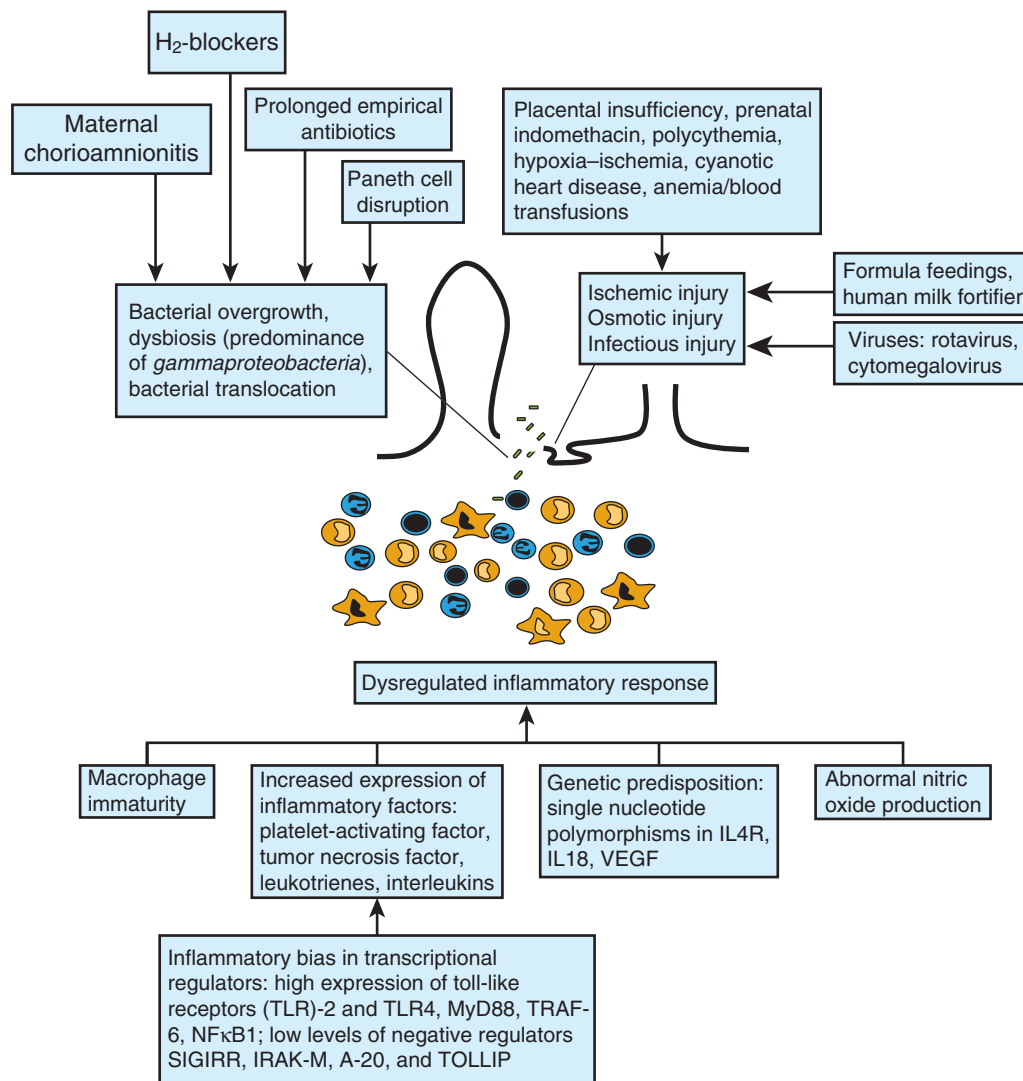

adherence) and the unique environmental exposures experienced by the preterm infant. Almost universally, preterm infants experience delayed enteral feedings, are exposed to early and prolonged broad-spectrum antibiotics, and are introduced to residential hospital flora (Elgin et al., 2016). Each of these factors contributes to delayed intestinal colonization by commensal, nonpathogenic bacteria, a predominance of pathogenic bacteria, and a lack of microbial diversity.

Necrotizing Enterocolitis

NEC is a devastating GI disease predominantly observed in preterm infants. The pathogenesis is complex and not well-understood. Current evidence suggests that NEC occurs in the preterm intestine when a dysfunctional or anatomically disrupted epithelial barrier allows bacterial translocation into the bowel wall, where these bacteria and their products induce a highly exaggerated and dysregulated inflammatory response. Fig. 72.6 links some of the clinical antecedents and plausible pathophysiologic events in NEC. In this schematic, critical host factors (prematurity), environment (ischemic/osmotic/infectious factors/agents that can produce mucosal injury), and agent factors (bacterial overgrowth, dysbiosis with proteobacterial blooms) are required. As discussed, the preterm infant possesses and experiences multiple perturbations to postnatal intestinal and immune development, all of which probably work in concert with one another to increase the vulnerability of the preterm infant to NEC. Just a few examples that illustrate this are the increased prevalence in formula-fed infants (lack of exposure to the bioactive compounds found in breast milk), the association of increased proteobacterial blooms observed in the microbiome composition in infants who developed NEC versus control infants (Claud et al., 2013; Morrow et al., 2013; Gritz and Bhandari, 2015; Lu and Ni, 2015; Warner et al., 2016), the reduction of NEC with the use of probiotics (Neu, 2014; Patel and Denning, 2015), and the increased incidence of NEC after exposure to prolonged antibiotics (delayed bacterial colonization with preference for pathogenic microorganisms) and to H₂ blockers (decrease gastric acidity, thus dampening one component of the first line of defense against pathogenic antigens provided by the intestinal tract) (Guillet et al., 2006; Cotten et al., 2009).

Atopic Diseases

The incidence of allergic diseases has dramatically increased over the past several decades in developed countries. A potential mechanism for this phenomenon has been termed the *hygiene hypothesis* (Bach, 2002; von Mutius, 2007). In this model, interaction with microbes and subsequent colonization by these organisms are essential in training mucosal immunity. With colonization of a diverse microbial population, the newborn shifts from a predominant Th2 cellular response (conditioned during fetal development to prevent maternal rejection of the fetus) (Morein et al., 2007) to a Th1 cellular response. However, in developed countries with improved hygiene and sanitation, the diversity of microbes in the intestinal ecosystem is lacking, and Th2 cellular responses continue to dominate (Tlaskalova-Hogenova et al., 2002). Supporting the vital contribution that the intestinal ecosystem plays in development of allergic responses are the observations of different colonization patterns observed in atopic subjects versus healthy controls (Bjorksten, 2004; Vaarala et al., 2008) and the reduction of atopic diseases with probiotic supplementation (Bjorksten, 2005). Other defects in mucosal immunity observed are that allergic

individuals have increased intestinal permeability and a deficiency of IgA.

Inflammatory Bowel Disease, Celiac Disease, and Type 1 Diabetes

Alterations in several areas of innate mucosal immunity play a significant role in the pathogenesis of Crohn's disease, celiac disease, and type 1 diabetes mellitus. Individuals with Crohn's disease have impaired intestinal barrier function, differential expression in TLR3 and TLR4, and Th1-dominated cellular responses. Differential expression in TLRs and Th1-dominated cellular responses probably contribute to the inappropriate, excessive inflammatory response to antigenic stimuli (toward *both* commensal and pathogenic bacteria), which is one of the hallmarks of this disease (Neurath et al., 2002; Macdonald and Monteleone, 2005; Sartor, 2008). An imbalance in Th1/Th2 cellular responses in Crohn's patients is further suggested by the finding that a genetic mutation in the

NOD2 gene, produces a protein that in its native form inhibits TLR2 activation, and is more common in patients with Crohn's disease than in controls (O'Neill, 2004; Strober et al., 2014). Impaired intestinal barrier function has been well described in Crohn's disease, though whether barrier defects are initiating events or amplifiers of the pathogenesis remains controversial.

The presence of a "leaky gut" may be important in the pathogenesis of autoimmune diseases such as celiac disease and type 1 diabetes mellitus. The process by which a breach in intestinal barrier function leads to celiac disease has become the generic disease model of intestinally mediated autoimmune disorders. Gliadin (the protein in wheat, barley, and rye) activates myeloid differentiation primary-response gene 88, which, in turn, upregulates the release of zonulin. Zonulin upregulation opens the TJCS, allowing for intraepithelial passage of gliadin into the intestinal submucosa to interact with effector immune cells and increase the production of proinflammatory cytokines, ultimately leading to intestinal inflammation and cell damage. Removal of gluten from the diet

halts this process, allowing for restoration of intestinal barrier function and intestinal recovery (Stein and Schuppan, 2014). The interplay among altered intestinal bacterial colonization, impaired barrier function, and a dysregulated proinflammatory response has also been implicated in the pathogenesis of type 1 diabetes mellitus (Mejia-Leon and Barca, 2015). Similar to subjects with Crohn's disease, compared with controls, individuals with type 1 diabetes mellitus have impaired intestinal barrier function (Li and Atkinson, 2015). Altered barrier function has also been shown in animal models that eventually develop diabetes. Diabetic animals have decreased expression of claudin, an important protein in TJ complexes, before the onset of disease. Finally, examination of intestinal biopsies from children with type 1 diabetes mellitus demonstrated an increased presence and expression of inflammatory cells and biomarkers (e.g., HLA class II molecules, intercellular adhesion molecule-1, IL-4, IL-1 α) within the villus architecture.

Obesity

Altered bacterial colonization patterns are evident in obesity. In animal models of genetic obesity, obese mice have distinctly different microbial colonization patterns compared with their lean littermates, with bacteria counts higher in Firmicutes and lower in Bacteroidetes. These microbial shifts are also seen in diet-induced animal models of obesity by placing the mice on a prolonged Western diet (Reinhardt et al., 2009). In humans, childhood obesity is increased in formula versus breastfed infants. In addition, as discussed earlier, different microbial colonization patterns exist between these two groups, suggesting that their ecosystem may play a role in the propensity for obesity. In a longitudinal study of childhood obesity, infants who later developed obesity, compared with infants who maintained a normal weight in childhood, had a fecal microbial pattern that contained lower concentrations of *Bifidobacterium* and higher concentrations of *Staphylococcus aureus*. Obesity has been associated with low-grade chronic inflammation; thus the reduction of the commensal organism *Bifidobacterium* and the increased presence of the pathogenic organism *Staphylococcus aureus* may, in part, contribute to the pathogenesis of chronic inflammation (Kalliomaki et al., 2008).

The intestinal ecosystem is an important modulator of the host's metabolic activities, some of which are important to the pathogenesis of obesity. Metagenomic studies of the microbiota in obese patients demonstrate an increased presence of genes that are involved in energy harvest. Other metabolic pathways mediated by the microbiota include increased hepatic lipogenesis, for example, decreased fatty acid oxidation in skeletal muscle and lipopolysaccharide-mediated chronic inflammation in adipose tissue (Reinhardt et al., 2009).

Conclusion

The GI tract serves many complex nutritional and immune functions critical for survival. The morphologic development of the intestinal tract to serve these specialized functions begins in early embryogenesis and continues throughout childhood. Exposure to amniotic fluid followed by postnatal exposures to human milk, formula, and environmental microorganisms is essential for the continued anatomic differentiation of the intestinal tract and development of mucosal immunity. Ultimately, multiple layers of immunologic defenses and a balance between oral tolerance and inflammatory responsiveness are established and maintained throughout the life of the host. Perturbations to this balance or to any component of the multiple layers of mucosal defenses increase the vulnerability of the host to atopic diseases, autoimmune disorders, or conditions mediated by chronic, unregulated inflammation.

Abdominal Wall Defects

DANIEL J. LEDBETTER, SHILPA CHABRA, AND PATRICK J. JAVID

KEY POINTS

- Omphalocele is a congenital midline abdominal wall defect of the umbilical region. The bowel, liver, and other organs that herniate out of the abdomen are covered by a membrane. The umbilical cord inserts into the omphalocele membrane.
- Gastroschisis is a congenital abdominal wall defect located just to the right of the umbilicus. The bowel that herniates out of the abdomen is not covered by a membrane.
- Fetuses and newborns with an omphalocele have a high risk of associated anomalies, especially chromosomal abnormalities and cardiac malformations.
- Fetuses and newborns with a gastroschisis have a low risk of associated anomalies, except for a 10%–25% risk of intestinal atresia.
- The clinical outcomes of patients with omphalocele are mainly determined by their associated anomalies.
- The clinical outcomes of patients with gastroschisis are mainly determined by their intestinal function.

This chapter discusses some of the congenital and acquired abdominal wall problems seen in newborns. The chapter begins with a brief review of abnormalities of the umbilical cord seen on prenatal imaging; this is followed by a discussion of abnormalities of the umbilicus seen after birth. The remainder of the chapter is a review of congenital abdominal wall defects and hernias. It concentrates on gastroschisis and omphalocele, which are the two most common congenital abdominal wall defects seen in the neonatal intensive care unit (NICU). This discussion is followed by a brief review of less common congenital abdominal wall defects. The chapter finishes with a brief consideration of abdominal wall hernias.

Umbilical Cord Abnormalities

The umbilical cord is the direct connection between the placenta and the fetus. It normally consists of an umbilical vein and two umbilical arteries encased in a gelatinous matrix known as Wharton jelly that is covered with a layer of amnion. Abnormalities of the umbilical cord have become more frequently recognized as prenatal imaging has become more common and more detailed. Even when umbilical cord abnormalities are not problematic, they are often associated with other pathologic conditions that result in poor fetal and neonatal outcomes. Therefore when abnormalities of the

umbilical cord are found, it usually prompts further investigation of the fetus for chromosomal abnormalities and structural malformations. In addition, many fetuses with umbilical cord abnormalities will need more frequent evaluations of fetal well-being ([Moshiri et al., 2014](#)). Several umbilical cord abnormalities are reviewed later, although many more umbilical abnormalities have been described.

Noncoiled Umbilical Cord

Almost 5% of umbilical cords are noncoiled or hypocoiled, making it one of the most common umbilical cord abnormalities. The umbilical coiling index (UCI) was developed and gestational age standards determined to quantify the degree of umbilical cord coiling ([de Laat et al., 2005](#)). A fetus with a UCI less than the fifth percentile for gestational age has an increased risk of intrauterine growth restriction (IUGR), preterm labor, fetal distress during labor and delivery, meconium-stained amniotic fluid, stillbirth, and chromosomal aberrations ([Mittal et al., 2015](#)), although these relationships are controversial ([Khong, 2010](#); [Jessop et al., 2014](#)).

Single Umbilical Artery

A single umbilical artery is also a relatively common anomaly seen in 0.5%–1% of pregnancies ([Pomeranz, 2004](#); [Granese et al., 2007](#); [Jessop et al., 2014](#)). It is associated with stillbirth, IUGR, and multiple gestation ([Voskamp et al., 2013](#)). Although a single umbilical artery is not diagnostically specific or sensitive for any specific congenital anomaly, fetuses with a single umbilical artery are at an increased risk of congenital malformations, especially genitourinary malformations and chromosomal anomalies ([Voskamp et al., 2013](#)). When a single umbilical artery is discovered after birth, it is not clear if the newborns need specific evaluation beyond a routine physical examination ([Deshpande et al., 2009](#)).

Umbilical Vessel Dilatations

Focal dilatations of the umbilical vessels are much less common than a single umbilical artery. Focal dilatations of the umbilical vein are known as umbilical vein varices, and similar focal dilatations of the umbilical artery are known as umbilical artery aneurysms. Both conditions are rare but seem to be associated with fetal and chromosomal anomalies and also with an increased risk of adverse fetal outcomes ([Mankuta et al., 2011](#); [Doehrman et al., 2014](#)).

Umbilical Cord Cysts

Umbilical cord cysts can be true cysts that are epithelial-lined remnants of the vitelline duct, also known as the omphalomesenteric duct (Heifetz and Rueda-Pedraza, 1983) or allantois, which forms the urachus. Alternatively, umbilical cord cysts may be pseudocysts that are fluid collections in the cord not surrounded by epithelium (Sepulveda et al., 1999). Pseudocysts are more common than true cysts and their presumptive cause is either degeneration of Wharton jelly, pooling of cord edema, or liquefaction of an umbilical cord hematoma. Umbilical cord pseudocysts discovered during the first trimester are relatively common and often spontaneously resolve, but pseudocysts that persist into the second trimester are associated with fetal aneuploidy and malformations (Ross et al., 1997). Umbilical cord cysts are usually small but if they are large they may lead to compression of umbilical cord blood flow and require aspiration.

Umbilical Cord Hematomas

Umbilical cord hematomas may be a result of intentional or unintentional umbilical cord puncture during amniocentesis or less commonly occur spontaneously. Most umbilical cord hematomas do not cause any problems but some are of a size and position to impair blood flow through umbilical vessels (Sepulveda et al., 1995).

Umbilical Abnormalities

Umbilical abnormalities seen in newborns usually present with an umbilical mass or with umbilical drainage. The most common umbilical abnormality is acquired granulation/granuloma tissue. Other abnormalities include delayed separation of the umbilical cord, umbilical and periumbilical infections, and congenital remnants of the urachus and omphalomesenteric duct.

Delayed Separation of the Umbilical Cord

After birth the umbilical cord usually dries out and falls off within a week, but there is considerable variability in the timing of this separation. Some of the variability in umbilical cord separation depends upon how the cord is cared for after birth since bacterial colonization seems to play an important role in the process. This explains why cords that are treated with more intensive antiseptic regimens typically fall off later than cords that are simply kept clean and dry (Mullany et al., 2013).

There is no standard definition of “delayed separation of the umbilical cord,” but in the United States if cord separation takes more than 3 weeks then it raises concerns for immune deficiency, urachal anomalies, or infection (Razvi et al., 2001). Leukocyte adhesion deficiency should be suspected when a newborn presents with delayed cord separation and soft tissue infection around the umbilical stalk (van de Vijver et al., 2013). However, it is important to remember that most infections associated with the umbilical cord are not associated with immune deficiencies.

Umbilical and Periumbilical Infections

The lack of an epithelial barrier at the unhealed umbilicus, normal bacterial colonization of the skin, and potential contamination of the area during cord care make the umbilicus vulnerable to bacterial invasion. Newborns with unimmunized mothers and improper cord care are at risk for neonatal tetanus, which can be a significant

problem in less developed countries (Razvi et al., 2001; Khan et al., 2013).

More typical bacterial soft tissue infections of the periumbilical region are known as omphalitis. Omphalitis ranges in severity from simple cellulitis to necrotizing soft tissue infection of the abdominal wall. The severity of infection depends upon host defenses, the virulence of the infecting organism, and the depth of invasion. In developed countries the incidence of omphalitis is less than 1%, but in less developed countries the incidence is much higher (Sinha et al., 2015). Omphalitis is often a polymicrobial infection with *Staphylococcus*, *Streptococcus*, aerobic gram-negative rods, and anaerobes (Fraser et al., 2006). Treatment of omphalitis includes broad-spectrum antibiotics and, for invasive infections, surgical debridement of involved tissues. Omphalitis can be a serious infection causing life-threatening systemic sepsis. The infection can also spread up the umbilical vein and cause inflammation and thrombosis of the portal vein that may evolve into symptomatic portal hypertension years later (Fraser et al., 2006).

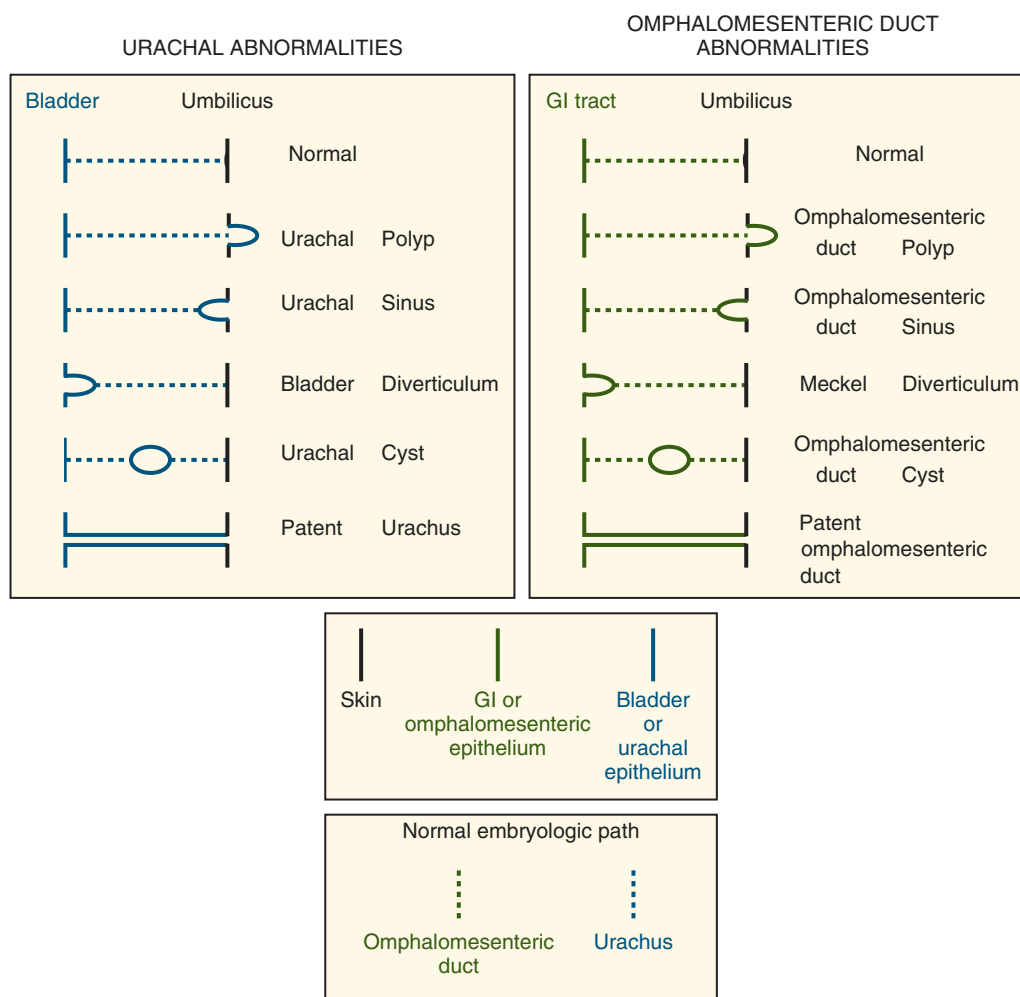

Umbilical Granulomas

Umbilical granulomas are the result of persistence and hypertrophy of the normal granulation tissue present at the base of the umbilicus after the umbilical cord separates away from the body wall. Histologically, granulomas are composed of fibroblasts and capillaries. Umbilical granulomas are the most common cause of an umbilical mass and umbilical drainage in an infant. Granulomas usually present as small (<1 cm in diameter) moist, pink, or red masses at the umbilicus. They may have serosanguineous drainage or fibrinous exudate that can be confused with the drainage of a soft tissue infection. Most small granulomas will spontaneously dry out, and the surrounding skin will contract and heal the umbilicus (Pomeranz, 2004; Snyder, 2007). Sometimes skin will grow over the granuloma and, as the inflammatory tissue shrinks, eventually result in a skin tag. These skin tags usually become smaller over time. Silver nitrate cauterization of the granulation tissue will eliminate or decrease the size of the umbilical granuloma and allow the skin to heal. Surgical excision is usually not necessary unless the lesions persists (Snyder, 2007).

Persistent Remnants of Urachus and Omphalomesenteric Duct

The urachus and omphalomesenteric duct are embryologic structures of the umbilical cord that normally regress or obliterate. When they persist, the persistent remnants may cause problems. The urachus is the remnant of allantois, which in the first weeks of development is a protrusion of the inner or endodermal surface of the embryo that connects to the yolk sac (which is in the body stalk), which later becomes the umbilical cord. The connection point of the allantois to the developing embryo is part of the hindgut that eventually becomes the bladder. The omphalomesenteric duct (also known as the vitelline duct) is also a protrusion of the inner endodermal surface of the embryo that connects to the yolk sac, but the connection point of the omphalomesenteric duct is to the midgut. The omphalomesenteric duct usually disappears by the ninth week of gestation.

Persistent remnants of the urachus and omphalomesenteric duct may present with drainage from the umbilicus, with an umbilical or periumbilical mass, or with both. The size and location of the persistent remnant often determine the clinical presentation more than the remnant's embryologic origin. The individual

• **Fig. 73.1** Schematic of the Types of Urachal and Omphalomesenteric Duct Abnormalities.

pathologic types of remnants are schematically represented in [Fig. 73.1](#) and include umbilical polyps, sinuses, fistulae, cysts, and bands. These types may exist alone or in combination.

Umbilical polyps are much less common than umbilical granulomas as a cause of an umbilical mass or umbilical drainage. An umbilical polyp is an epithelial remnant of the omphalomesenteric duct or the urachus that persists at the skin level and presents as a moist, bright red, round mass. The serous exudate or mucous secretions of the epithelium account for the umbilical drainage. Unlike the granulation tissue of an umbilical granuloma, the epithelium of an umbilical polyp will not respond to silver nitrate cauterization, and surgical excision is required.

A partial, persistent remnant of the urachus or omphalomesenteric duct that is open to the skin at the umbilicus is known as an urachal sinus or an umbilical (or omphalomesenteric) sinus (see [Fig. 73.1](#)). Similar to umbilical polyps, sinuses present with umbilical drainage and require surgical excision. A partial, persistent remnant of the urachus or omphalomesenteric duct that is open to the lumen of the bladder or gastrointestinal (GI) tract is known as a bladder diverticulum or Meckel diverticulum, respectively (see [Fig. 73.1](#)). A partial, persistent remnant of the urachus or omphalomesenteric duct that does not connect to the skin or the underlying bladder or bowel lumen is known as a urachal or omphalomesenteric cyst, respectively (see [Fig. 73.1](#)) and presents as a midline mass in the abdominal wall at or near the umbilicus. Cysts may also present

with increasing size, pain, tenderness, and fever if they become infected. Cysts require excision, although if infected they may first require incision and drainage and then interval excision.

A complete persistent remnant of the urachus or omphalomesenteric duct is a fistula between the umbilicus and bladder or bowel, respectively (see [Fig. 73.1](#)). When the fistula is connected to the bladder, it is known as a patent urachus, and it may drain urine. When the fistula is connected to the GI tract, it is known as an omphalomesenteric (or vitelline) duct fistula and may drain enteric contents. Treatment for fistulae includes surgical excision and closure of the bladder or bowel, respectively ([Snyder, 2007](#)).

Abdominal Wall Defects

This section reviews gastroschisis and omphalocele, which are the two most common abdominal wall defects seen in the NICU, and briefly discusses some less common abdominal wall defects.

Gastroschisis and omphalocele are similar in that both are congenital abdominal wall defects that present with herniation of abdominal contents outside of the body. Both entities require reduction of the herniated contents back into the abdominal cavity and closure of the abdominal wall defect. However, gastroschisis and omphalocele are distinct conditions with important differences in anatomy and associated conditions that account for their unique management and outcomes ([Fig. 73.2](#)).

| | GASTROSCHISIS | OMPHALOCELE |
|---------------------------------------|---|--|
| |  |  |
| Location of abdominal wall defect | Right of umbilical cord | Midline, includes umbilical cord |
| Covering membrane | No | Yes |
| Umbilical cord insertion | Normal | Into omphalocele membrane |
| Herniated organs | | |
| Bowel | Always | Common |
| Liver | Uncommon for more than an edge to be out | Common for large amount of liver to be out |
| Associated anomalies | | |
| Chromosomal | Rare | Common |
| Syndromes | Rare | Common |
| Cardiac | Uncommon, 2%–5% | Common |
| Bowel atresia | 10%–25% | Rare |
| Major determinant of clinical outcome | Condition and function of bowel | Associated anomalies |

• **Fig. 73.2** Gastroschisis Versus Omphalocele.

Gastroschisis

Gastroschisis is a circular abdominal wall defect just to the right of a normally inserted umbilical cord with herniation of a variable amount of intestine and possibly parts of other organs outside the abdominal cavity. There is no covering membrane, and the intestine is exposed directly to amniotic fluid prenatally and to the air after birth (see Fig. 73.2). It is unusual for a significant amount of liver to herniate out of a gastroschisis defect. Rarely, the gastroschisis defect is in a mirror-image position on the left side of the umbilicus.

Gastroschisis may be classified as either “simple” or “complex.” Gastroschisis is “complex” when there is an associated intestinal atresia, segmental or midgut volvulus, ischemic bowel, intestinal perforation, or necrotizing enterocolitis. Vanishing gastroschisis is a form of complex gastroschisis where the abdominal wall muscle around the gastroschisis defect closes in utero and strangulates the bowel (Fig. 73.3). Babies with vanishing gastroschisis may have

little or no viable bowel outside the abdomen and suffer from short bowel syndrome.

The prevalence of gastroschisis is 2.3 to 4.4 cases in 10,000 live births (Kirby et al., 2013). There is no gender predilection in gastroschisis, but the incidence is higher in Hispanic and non-Hispanic white families (Jones et al., 2016). For unknown reasons, the incidence of gastroschisis around the world is increasing. In the United States, the incidence nearly doubled from 1995 to 2005 (2.3 to 4.4 per 10,000 live births) (Parker et al., 2010), and there was a 30% increase in incidence from 1995 to 2005 to 2006 to 2012 (Jones et al., 2016).

Gastroschisis is usually an isolated defect that occurs sporadically. The etiology is probably multifactorial. The most consistent risk factor for gastroschisis is young maternal age. Mothers under the age of 20 years have a severalfold increased risk of carrying a baby with gastroschisis (Loane et al., 2007; Chabra et al., 2011; Skarsgard et al., 2015). Numerous other maternal factors have been linked with gastroschisis including recreational drugs, low body mass

• **Fig. 73.3** Vanishing Gastroschisis. Note that the gastroschisis defect has closed completely, leading to severely constricted mesenteric blood supply and intestinal atresia and a tiny, isolated blind loop on the outside of the abdominal wall. Inside the abdomen there is a proximal small bowel atresia that is completely separated away from the closed end of the remaining distal bowel.

index, cigarette smoking, antidepressants, unmarried status, and genitourinary infections during gestation (Centers for Disease Control and Prevention, 2007; Parker et al., 2010; Hook-Dufresne et al., 2015). The tendency of gastroschisis to occur in clusters suggests the influence of teratogens, and population-based studies have shown a higher incidence of gastroschisis in areas where a common agricultural chemical (atrazine) is used and surface water concentrations of atrazine are elevated (Mattix et al., 2007; Waller et al., 2010).

The embryology of gastroschisis is not completely defined; however, several theories have been postulated, including (1) failure of the lateral right ventral fold to unite with other body wall folds at the umbilicus or (2) failure of development of the umbilical coelom as the early gut elongates (Feldkamp et al., 2007; Sadler, 2010). There is no known specific genetic etiology for gastroschisis, although there are rare case reports of families with multiple affected offspring.

Unlike omphalocele, extraintestinal anomalies are not commonly associated with gastroschisis. In a large international study 4.5% of the participants had central nervous system anomalies, 2.5% had cardiovascular anomalies, 2.2% had limb anomalies, and 1.9% had kidney anomalies (Mastroiacovo et al., 2007). Anomalies of the intestine are the most common associated malformations in patients with gastroschisis. Nearly all babies with gastroschisis have intestinal malrotation, since the bowel did not return to the abdominal cavity normally during fetal development and had no chance for normal rotation and fixation to the retroperitoneum. Intestinal atresia occurs in 10%–25% of babies with gastroschisis (Kronfli et al., 2010; Ghionzoli et al., 2012) and is probably caused by the contracting abdominal wall (see Fig. 73.3) or associated bands that can impair blood flow to the bowel (Fig. 73.4).

With routine prenatal care in the developed world, about 90% of gastroschisis cases are diagnosed prenatally. The maternal alpha fetoprotein (AFP) level is usually elevated with fetal gastroschisis (Saller et al., 1994), and the diagnosis can be confirmed early in the second trimester by prenatal ultrasound. Diagnostic prenatal ultrasound findings of gastroschisis are extraabdominal loops of bowel without a covering sac.

Gastroschisis can be difficult to differentiate from a ruptured omphalocele. Findings that favor the diagnosis of gastroschisis rather than a ruptured omphalocele are a relatively small abdominal

• **Fig. 73.4** Gastroschisis. Gastroschisis with a band from mesentery to the umbilicus. The cotton-tipped applicator stick is beneath the band.

wall defect (usually <4 cm in diameter), the absence of liver protruding outside the body wall, and an umbilical cord that is normally inserted into the body wall just to the left of the defect.

Patients with gastroschisis are best cared for by a multidisciplinary team of maternal fetal medicine specialists, neonatologists, and pediatric surgeons. Prenatal consultation with this multidisciplinary group is strongly recommended. Fetuses with gastroschisis have a significant risk of IUGR, spontaneous preterm labor, and fetal demise (Carpenter et al., 1984; Netta et al., 2007; Santiago-Munoz et al., 2007; Barseghyan et al., 2012). Karyotype of the fetus is not routinely performed since there seems to be no specific genetic etiology of gastroschisis and the chromosomes are usually normal. Fetuses with gastroschisis are followed closely with ultrasounds every 2 to 3 weeks to evaluate the bowel anatomy and fetal growth.

The timing of delivery in gastroschisis remains controversial. Planned preterm delivery is believed by some to reduce postnatal intestinal complications and the incidence of intrauterine fetal demise; however, there are no high-quality data, and retrospective studies have conflicting results. A Cochrane review included only one randomized prospective study, which was too underpowered to resolve the issue, hence, additional research was recommended (Grant et al., 2013).

The argument against planned preterm delivery is bolstered by contemporary outcome studies that consistently demonstrate that preterm delivery is a major source of adverse outcome in infants with gastroschisis (Boutros et al., 2009; Maramreddy et al., 2009; South et al., 2013; Carnaghan et al., 2014; Overcash et al., 2014). In addition, the weekly prevalence of intrauterine fetal demise does not increase after 35 weeks' gestation (South et al., 2013). Therefore many centers, including our own, now advocate for delivery close to term.

There is a stronger consensus regarding the route of delivery for patients with gastroschisis, since cesarean section seems to offer no benefit to the baby or the mother (Segel et al., 2001; Salihu et al., 2004; Abdel-Latif et al., 2008). Cesarean section is reserved for standard obstetric indications.

After delivery, the perfusion of the herniated contents should be carefully evaluated. If bowel ischemia or infarction is suspected, then immediate surgical consultation is indicated for bowel detorsion or even emergency enlargement of the gastroschisis defect. If the viscera are well perfused, it is important to next place a clear plastic bag over the exposed bowel as a temporary covering to minimize evaporative heat and fluid loss. The bag may be placed over the

• **Fig. 73.5** Gastroschisis. Gastroschisis with herniated bowel in a Silastic (Dow Corning) silo that has been sewn into a surgically enlarged abdominal wall defect.

entire lower body from the nipples to the feet. A peripheral intravenous line is placed to start intravenous fluids and broad-spectrum antibiotics. An orogastric or nasogastric tube is placed to suction and empty the stomach. The baby should be kept warm and dry throughout the initial resuscitation.

After initial resuscitation and stabilization, the patient is then transported to a NICU with pediatric surgical services. Endotracheal intubation is not required for transport unless indicated for respiratory support. The baby should be placed with the right side angled slightly down to prevent kinking of the mesentery and maximize blood flow to the bowel. The orogastric or nasogastric tube should remain on low intermittent suction during transport. Bowel perfusion should be monitored.

The goal of surgical repair in gastroschisis is safe reduction of the eviscerated contents and eventual closure of the abdominal wall. Multiple surgical options exist to accomplish this goal, and both primary repair and staged repair are acceptable alternatives.

Traditional primary repair of gastroschisis involves closing the fascial defect with sutures in the operating room under general anesthesia. This is performed while monitoring intragastric or bladder pressure to make sure that the closure does not cause abdominal compartment syndrome. In some cases, a prosthetic patch is required to close the defect.

Staged repairs with initial silo coverage of gastroschisis are also an accepted procedure that requires later reduction of the herniated bowel and closure of the abdominal wall. Silos may be made from Silastic (Dow Corning) or other plastic sheeting and sewn circumferentially to the fascial edges of the original or extended gastroschisis defect (Fig. 73.5). Another technique is to use a premade, spring-loaded Silastic silo that is manufactured with different diameters and can be inserted into the gastroschisis defect at the bedside (Fig. 73.6). Once a silo is placed, the bowel gradually reduces over several days into the abdominal cavity by either gravity alone or external pressure. When the reduction takes more than 7–10 days the risk of the silo dehiscence from the abdominal wall increases. Delayed primary closure of the fascia is performed when the abdominal contents have almost completely reduced into the abdominal cavity.

Primary umbilical cord closure is a relatively new technique that uses the patient's own umbilical cord stump as a biologic dressing to seal the gastroschisis defect without attempting a primary fascial closure (Sandler et al., 2004; Choi et al., 2012). In this

• **Fig. 73.6** Gastroschisis. Gastroschisis with herniated bowel in pre-formed spring-loaded Silastic (Dow Corning) silo that has been placed into the gastroschisis defect.

• **Fig. 73.7** Gastroschisis. Gastroschisis after reduction of herniated bowel into the abdomen and suture-less coverage of the gastroschisis abdominal wall defect with the coiled umbilical cord.

technique, the cord is left relatively long at delivery, and the eviscerated contents are reduced into the abdominal cavity while monitoring intraabdominal pressure. The fascial and skin defect are then covered with the coiled umbilical cord that is secured into place with a bandage (Fig. 73.7). In most cases, the gastroschisis defect contracts, and the skin heals beneath and around the cord within 14 days. Using this technique, some children will have a persistent umbilical hernia that can be repaired at 3 to 4 years of age.

Despite many retrospective studies, database analyses, and metaanalyses, it is unclear which surgical approach is best for any individual baby with gastroschisis (Mills et al., 2010; Alali et al., 2011; Bradnock et al., 2011; McNamara et al., 2011; Murthy et al., 2014; Stanger et al., 2014; Emami et al., 2015; Ross et al., 2015). Many studies suffer from significant selection bias and do not separately analyze patients with complex gastroschisis, thereby

making outcome comparisons difficult. The only randomized, prospective study to evaluate primary versus delayed fascial closure was published in 2008 and did not find significant outcome differences between techniques (Pastor et al., 2008). A recently published metaanalysis suggests that delayed primary repair may be associated with improved outcome measures when studies with selection bias are eliminated from the analysis (Kunz et al., 2013). The outcomes from contemporary literature suggest that both primary and delayed closure strategies are safe and effective.

The choice of primary fascial closure versus delayed repair using a silo may be less relevant in the era of the primary umbilical cord closure. Primary umbilical cord closure is successful in most babies with gastroschisis, may be performed at the bedside, does not always require general anesthesia, and reduces duration of mechanical ventilation (Riboh et al., 2009; Emami et al., 2015). In our experience, the technique is associated with shorter NICU stays and shorter time to initiation of enteral nutrition (Chesley et al., 2015).

Babies with uncomplicated gastroschisis have average hospital stays of 4 to 6 weeks, which is largely due to their inability to tolerate full enteral feedings. Babies with complicated gastroschisis often have much longer hospital stays.

Outcomes for children born with gastroschisis in the developed world are excellent. Survival of greater than 95% can be expected in cases of uncomplicated gastroschisis. Infants with complex gastroschisis are at higher risk for overall mortality, short bowel syndrome, bowel obstruction, necrotizing enterocolitis, and the need for home parenteral nutrition after discharge (Bergholz et al., 2014). While only a small minority of babies with gastroschisis will need extensive bowel resection, gastroschisis remains a leading etiology of short bowel syndrome in most series of children with intestinal failure (Modi et al., 2007; Javid et al., 2010). Despite the excellent overall outcomes for gastroschisis in the developed world, mortality remains very high in the developing world (Ford et al., 2016).

Long-term outcomes in gastroschisis are favorable. Most patients will have normal GI function and normal neurodevelopmental outcomes (Gorra et al., 2012; Harris et al., 2016). Even though gastroschisis is almost always associated with intestinal malrotation, the risk of midgut volvulus later in life is low, probably because intraabdominal adhesions that result from the newborn reduction and closure limit the ability of the bowel to twist. These patients may develop hernias at the site of repair. Finally, although boys with gastroschisis commonly have undescended testicles, about 50% of patients will undergo spontaneous testicular descent and not require an operation.

Omphalocele

An omphalocele (known as exomphalos in the United Kingdom) is a midline abdominal wall defect with herniation of bowel and possibly liver and other organs outside the abdomen. The herniated contents are covered with a membrane consisting of peritoneum on the inside, amnion on the outside, and Wharton jelly between those two layers. The umbilical cord inserts into the membrane rather than the abdominal wall (see Fig. 73.3). The omphalocele membrane is usually intact, but occasionally it ruptures and the herniated visceral contents are not covered. Cases of ruptured omphalocele can be confused with gastroschisis, but there are distinct differences (see the section on [Gastroschisis](#)).

Some authors make a distinction between an omphalocele and a hernia of the umbilical cord. In a hernia of the umbilical cord,

the umbilical ring is reportedly normal. Since there is only an open umbilical ring and no deficiency of abdominal wall, the surgical repair is much easier. More importantly, unlike newborns with omphaloceles, newborns with a hernia of the umbilical cord reportedly have a low risk of associated anomalies. However, the clinical differentiation can be difficult, and some physicians do not make a distinction between the two conditions (Raju et al., 2015).

The incidence of omphalocele is estimated to be between 1.5 and 3 per 10,000 births (Marshall et al., 2015). The incidence of omphalocele has been stable over time, unlike the incidence of gastroschisis, which is increasing (Kirby et al., 2013; Marshall et al., 2015). Most cases of omphalocele are sporadic, but there are rare familial occurrences (Frolov et al., 2010). Risk factors for omphalocele include a maternal age of less than 20 years or greater than 40 years (Byron-Scott et al., 1998).

Normal development of the abdomen involves the flat, three-layered embryonic disk folding from top, bottom, and both sides to meet at the umbilical ring surrounding the umbilical cord to form the cylindrical torso during the fourth to fifth week of gestation. The GI tract also begins to grow very rapidly early in the first trimester and, because there is not enough room in the abdominal cavity, there is a normal herniation of bowel through the umbilical ring into the umbilical cord. By 10 to 12 weeks' gestation, the bowel normally returns to the abdominal cavity in a precise pattern of rotation and then fixation to assume its final position. The embryology of omphalocele is not completely understood but is thought to involve incomplete abdominal wall folding and failure of the intestinal tract to return from the umbilical cord (Sadler, 2010; Torres et al., 2015).

In contrast to the relatively low risk of associated anomalies in babies with gastroschisis, babies with omphalocele commonly have associated anomalies that play a major role in how these patients are managed and in their eventual outcome (Lakshminarayanan and Lakhoo, 2014). Chromosomal anomalies such as trisomy 13 and 18 are common, especially in fetuses diagnosed early in gestation (Prefumo and Izzi, 2014; Marshall et al., 2015). In addition, other congenital malformations are common, especially congenital heart disease, which may occur in up to 50% of newborns with omphalocele (Marshall et al., 2015). Finally, omphalocele is a component of many different syndromes of congenital malformations, including Beckwith–Wiedemann syndrome, which occurs in 6% of newborns with an omphalocele and in up to 10%–20% of those newborns thought to have an isolated omphalocele on prenatal evaluation (Corey et al., 2014).

The prenatal diagnosis of omphalocele may be suspected when maternal serum AFP levels are elevated or when there is fetal aneuploidy, but the definitive diagnosis is made by prenatal ultrasound. The prenatal ultrasound findings of omphalocele are abdominal organs herniated outside the abdominal cavity that are covered with a membrane and an abnormal insertion of the umbilical cord into the membrane rather than into the abdominal wall (Prefumo and Izzi, 2014). The prenatal ultrasound diagnosis of omphalocele can be reliably made after the first trimester when the bowel that is normally herniated into the umbilical cord returns to the abdominal cavity. Since the liver is never normally outside the abdominal cavity, the finding of liver outside the abdomen potentially allows an earlier and more accurate diagnosis of omphalocele (Tassin and Benachi, 2014). It is also important to note the presence or absence of liver within the omphalocele, since the absence of liver is associated with a higher risk of other anomalies (Prefumo and Izzi, 2014).

The prenatal management of omphalocele includes evaluation for associated anomalies and monitoring of fetal growth. All fetuses with suspected omphalocele should have an imaging evaluation for structural anomalies. Because of the high risk of congenital heart disease, fetal echocardiography is indicated. Prenatal monitoring of fetal growth is done because of the risk of IUGR. Other specific evaluations for associated pulmonary hypoplasia and the relative size of the defect are advocated to provide improved prenatal counseling about the expected hospital course and the long-term prognosis (Danzer et al., 2012b).

Other obstetric care, including the timing and method of delivery, is usually determined by traditional maternal and fetal factors rather than by the presence of the omphalocele. Specifically, there is usually no benefit (and there is potential harm) with preterm delivery (Porter et al., 2009). Cesarean section is not indicated for most fetuses with an omphalocele, although for fetuses with large defects containing liver (i.e., giant omphaloceles) it has been advocated and is commonly performed (Segel et al., 2001; Biard et al., 2004) to avoid rupture of the sac.

After delivery, the initial evaluation and resuscitation of a baby with an omphalocele follow the same priorities and sequence as for all newborns. During the initial resuscitation, a newborn with an omphalocele should be handled carefully to prevent the omphalocele membrane from tearing. After the initial resuscitation, the omphalocele should be inspected to confirm that it is intact and then covered with a nonadherent dressing to protect the sac.

The membrane of a ruptured omphalocele can sometimes be repaired (Akakpo-Numado et al., 2012), but that is not always possible. When a ruptured omphalocele cannot be repaired, the care of the patient and the abdominal wall defect follows a pathway more similar to the care of newborns with gastroschisis, although surgical closure is usually more complicated, and both mortality and morbidity are high (Yamagishi et al., 2007).

Newborns with omphaloceles, especially large omphaloceles, may have respiratory insufficiency caused by pulmonary hypoplasia and pulmonary hypertension (Baerg et al., 2015), and they may require respiratory support (Panitch, 2015). In addition, those babies with associated Beckwith–Wiedemann syndrome may have hypoglycemia and require supplemental glucose. An early evaluation for possible associated anomalies, especially congenital heart disease, is required to diagnose conditions that may need further treatment.

The goal of operative treatment of omphalocele is to reduce the herniated organs back into abdomen and close the abdominal wall. Surgical closure of an omphalocele is not an emergency as long as the omphalocele membrane remains intact, so there is time for an evaluation for associated anomalies and supportive treatment of other significant problems.

When the omphalocele is relatively small (Fig. 73.8), and the baby is otherwise stable, an early operation with excision of the omphalocele membrane, reduction of the herniated organs, and closure of the abdominal wall muscles is usually done. When the defect is too large to safely reduce the organs and close the abdominal wall in a single operation, the repair can be staged with an initial silo placement, followed by serial reduction of the silo, and finally closure of the abdominal wall. This strategy is almost identical to the staged approach often used for gastroschisis (Ledbetter, 2012). The early, staged approach is not always successful if the abdominal defect is large and there is a significant amount of herniated contents that need to be reduced into a relatively small abdominal cavity. In addition, reducing the abdominal contents may impair ventilation, which can be a critical problem in the setting of underlying pulmonary insufficiency (Tsakayannis et al., 1996).

• **Fig. 73.8** Small Omphalocele. Note the umbilical cord inserting into the intact omphalocele membrane.

To avoid the stress of neonatal surgery, the repair of an omphalocele can be delayed until the baby is bigger and more able to tolerate a major operation. This delayed approach can be accomplished when the sac remains intact and is best accomplished when the membrane is treated with topical agents that allow the sac to epithelialize (Ledbetter, 2012). A variety of topical agents have been used to treat the omphalocele sac (Whitehouse et al., 2010; Ein and Langer, 2012; Nicoara et al., 2014). As the sac is healing, the baby is growing. Growth of the abdominal cavity allows the herniated abdominal organs to reduce back into the abdomen with gravity alone or with additional external compression. In addition, lung growth will improve the baby's ability to tolerate an operation. The eventual repair of the abdominal wall can be done months or even years later (Lee et al., 2006).

Although there is no consensus definition of giant omphalocele, it is often described as omphaloceles with fascial defects greater than 5 cm in diameter or those containing large amounts of liver (Whitehouse et al., 2010). Topical treatment and delayed repair are important tools in the management of giant omphaloceles when there is no reasonable chance for early reduction and primary closure. We recommend topical silver sulfadiazine, as it is easy to use, safe, and effective (Lee et al., 2006). Any topical agent used has the potential of being systemically absorbed and potentially harmful to the baby. For example, mercurochrome can lead to mercury poisoning, and iodine has been associated with hypothyroidism and hyperthyroidism. Silver toxicity is a theoretical concern of using silver sulfadiazine or other silver-containing wound care products; however, clinical signs and symptoms have not been reported.

The survival and long-term outcomes of fetuses or newborns with omphaloceles are mainly determined by the severity of associated anomalies (Gamba and Midrio, 2014; Marshall et al., 2015). Babies with giant omphaloceles have increased mortality and morbidity because of the large abdominal wall defect and associated pulmonary hypoplasia and pulmonary hypertension (Biard et al., 2004; Danzer et al., 2012a, 2015).

Other Abdominal Wall Defects

Body Stalk Anomaly

Body stalk anomaly, which is also known as the limb–body wall complex, is a rare, severe body wall defect of the abdomen and

chest, which is almost always lethal. Prenatal ultrasound can visualize the herniated organs from the chest and abdomen that are covered by a membrane. In addition, a fetus with a body stalk anomaly will usually have scoliosis, and other malformations are common. The umbilical cord is either very short or absent. If the umbilical cord is absent, there are direct vascular connections between the fetus and placenta. It is important to recognize body stalk anomaly on prenatal imaging so that families can receive appropriate prenatal counseling (Pakdaman et al., 2015).

Bladder Exstrophy

Bladder exstrophy is an anomaly of the lower abdominal wall, pelvis, and pelvic organs in which an open bladder makes up the lower part of the anterior abdomen. The open bladder is accompanied by a separation of the pubic symphysis. It is a rare anomaly, with an incidence of 3 to 5 cases in 100,000 births, and it occurs at least twice as often in boys compared with girls (Jayachandran et al., 2011). The etiology is unknown, and it is grouped into the exstrophy–epispadias complex of anomalies. Surgical treatment is required but is not an emergency, so patients can be transferred to specialized centers for definitive care. Early management consists of protecting the exposed bladder mucosa from injury by applying a nonadherent dressing. Evaluation for associated anomalies includes ultrasound for associated upper urinary tract anomalies and an abdominal radiograph to assess the degree of pelvic bone separation.

Cloacal Exstrophy

Cloacal exstrophy is another anomaly grouped into the exstrophy–epispadias complex of anomalies. It is also known as OEIS complex—Omphalocele, Exstrophy, Imperforate anus, Spinal dysraphism—that describes its usual features. It is a rare anomaly, occurring in about 1 in 100,000 births, and is associated with the 1p36 deletion (Feldkamp et al., 2011). Most patients present with an abdominal wall defect that at its cephalic aspect consists of an omphalocele. The omphalocele is in continuity with a more caudal complex exstrophy of two lateral bladder halves joined to a central bowel exstrophy called a cecal plate. This exstrophy complex is accompanied by pubic symphysis diastasis (similar to that seen in bladder exstrophy) and imperforate anus. It may be associated with spinal dysraphism.

Bowel peristalsis and abdominal pressure often lead to prolapse of the terminal ileum and the distal colon/hindgut lumens that are normally attached to the cecal plate. Early management consists of a nonadherent bandage to the exposed bladder and bowel mucosa. Surgical reconstruction is complex and often done in stages. Overall survival is high, but there is substantial long-term morbidity, including abnormal anorectal, urinary tract, and neurologic function (Versteegh et al., 2013).

Prune Belly Syndrome

Prune belly syndrome (PBS), also known as Eagle–Barrett syndrome, is a rare condition notable for complete or partial lack of abdominal wall muscle and severe genitourinary abnormalities. A major cause of mortality in newborns with PBS is pulmonary hypoplasia, while comprising a major component of long-term morbidity are urinary tract abnormalities that often result in end-stage renal disease (Seidel et al., 2015; Arlen et al., 2016). A variety of reconstruction procedures of the abdominal wall have been described that reportedly improve bladder and GI function as well as improve the appearance (Hassett et al., 2012).

Abdominal Wall Hernias

A hernia exists when the contents of a body cavity extend through the normal wall of that cavity. Abdominal wall hernias are conditions where intraabdominal contents protrude through the normal muscle and fascial layers of the abdominal wall. The congenital abdominal wall defects discussed in the previous section are types of abdominal wall hernias. In contrast to those conditions that present prenatally or immediately after birth, this section will briefly discuss other abdominal wall hernias that usually present after birth, although their anatomic cause may be due to an abnormality of development.

Diastasis Recti

Although diastasis recti is a normal variant and not a hernia, it is often mistaken for an abdominal wall hernia, and so it is discussed here. The central section of a normal anterior abdominal wall consists of two rectus abdominus muscles that extend from the ribs to the groin. Between the rectus muscles there is an extension of the rectus muscle fascia, known as the linea alba, that joins the two rectus muscles and creates a solid abdominal wall. A visible separation of the rectus muscles with an intact linea alba fascia is known as diastasis recti or rectus abdominis diastasis. In this condition, the body wall musculofascial layer is intact, but the midline bulge of the linea alba fascia when the abdominal muscles contract is often mistaken for a hernia.

Diastasis recti is readily apparent on physical examination as midline bulging of the abdominal wall between the xiphoid process and the umbilicus. Imaging studies are not indicated. Although diastasis recti may be a cosmetic problem in a postpartum woman, the condition is not a pathologic problem in an infant and will typically be less noticeable after normal growth. Surgical treatments have been advocated for adults to improve the appearance of the abdominal wall but are not indicated in infants and children (Akram and Matzen, 2014).

Epigastric Hernia

Epigastric hernias are small fascial defects in the linea alba, the midline fascia between the rectus abdominis muscles, through which preperitoneal fat can herniate. Because they are typically only a few millimeters in diameter, the fascial defects are usually too small to palpate, but preperitoneal fat can herniate out like a mushroom with only a small stalk traversing the defect and a larger cap in the subcutaneous tissue that may be visible and palpable (Coats et al., 2000). Epigastric hernias are usually asymptomatic, and surgical repair can be delayed until later in life.

Umbilical Hernia

The umbilical ring is the normal fascial layer that surrounds the umbilical cord going through the abdominal wall. It represents the junction of superior, inferior, and lateral body wall folds. An umbilical hernia is a protrusion of bowel or omentum through an open umbilical ring, producing a bulge at the umbilicus. The umbilical ring normally closes after birth, but it may take months or years to become too small for bowel to herniate through the abdominal wall.

Umbilical hernias are usually not present at birth or in the first few days of life but may become noticeable after a few weeks. They are more common in infants born prematurely and much more common in African-American infants than in Caucasian infants. Most umbilical hernias are sporadic, but for unknown reasons some families have an increased risk. Umbilical hernias are more noticeable when the intraabdominal pressure

increases with crying or straining, but the hernias usually do not cause pain or distress. The great majority of umbilical hernias close spontaneously before school age, and symptoms are uncommon early in life so surgical repair is usually delayed until 3 to 5 years of age or until symptoms develop (Kelly and Ponsky, 2013).

Inguinal Hernia and Hydrocele

Inguinal hernias are the bulging of intraabdominal contents through the abdominal wall in the groin (Fig. 73.9). In adults this may be the result of abdominal wall muscular injury or weakness, but in infants the hernia is a result of a persistent congenital protrusion of the peritoneum through the normal internal and external ring openings of the abdominal wall muscles. This peritoneal protrusion is known as a patent processus vaginalis, and as it crosses the abdominal wall it is immediately adjacent to the spermatic cord structures in boys and the round ligament of the uterus in girls. In boys the processus vaginalis is the path of normal descent of the testis, and it normally closes except for a small pouch around the testis. When it remains open and is large enough, then pressure in the abdomen may allow intraabdominal contents through the abdominal wall, perhaps all the way into the scrotum. When organs or parts of organs protrude, it is called a hernia, and when only fluid goes into the processus vaginalis, it is known as a hydrocele (Kelly and Ponsky, 2013).

Roughly 1% of children will have an inguinal hernia. Hernias are much more common in boys than in girls (Grosfeld, 1989). Hernias are also much more common in premature babies compared to term babies (Peevy et al., 1986). Unlike umbilical hernias, inguinal hernias do not spontaneously heal, and they tend to get larger with time. The major risk of an inguinal hernia is the possibility of strangulation of the hernia contents with life-threatening intestinal ischemia. An additional complication would be compression of blood supply to a herniated gonad by the protruding hernia with subsequent loss of testicle or ovary. Strangulation only occurs

when hernias are incarcerated, i.e., when the contents are not reducible back into the abdomen. Therefore a nonreducible or incarcerated inguinal hernia requires urgent surgical evaluation. In otherwise healthy infants, inguinal hernias are repaired electively, soon after their diagnosis, since the operation is well tolerated and the risk of anesthesia is low (Davidson et al., 2016). Premature infants are prone to apnea after general anesthesia, so the ideal timing of operation in this group is controversial (Duggan et al., 2015; Sulkowski et al., 2015). A baby who has an inguinal hernia has an increased risk of developing a contralateral hernia later in life, but the risk may not be high enough to justify routine “prophylactic” hernia repair (Wenk et al., 2015).
